In 1974 Academician Boris Astaurov died from a heart attack—a great loss for Soviet biology. His death was probably hastened by strong political pressures induced by the defection of one of the senior research scientists from his institute. As director, Astaurov had recommended that this good research worker present a paper at an international conference in Italy. The man asked for political asylum and did not return to the USSR. In such cases, the official bureaucracy makes directors personally responsible. Special Academy commissions started to 'investigate' (with active participation by Dubinin) all aspects of the ideological and moral atmosphere of Astaurov's institute. Some senior members of his staff were demoted or dismissed, and Astaurov's health suffered.

Not long before his death, Astaurov, as a member of the Editorial Board of a popular scientific journal *Priroda* (Nature), recommended that it publish a translation of the article "Man as a Biological Species" by Professor Ernest Mayr, a prominent American zoologist and population geneticist. The article did not ignore the social aspects of formation of human personality, but it considered all characteristics and qualities of individuals to be a result of the interaction of genotype and environmental and social influences.

Mayr's article provoked interesting discussion in *Priroda;* several anthropologists and philosophers supported his views. Dubinin did not join in the *Priroda* discussion, but instead attacked Mayr's article in a paper published in a philosophy journal where he insisted that all the spiritual aspects of human life are outside biology or genetics. He labelled Mayr's synthetic, social and biological approach as "reactionary" and "racialist".

Reply published

The average publication time in Soviet journals, including popular scientific ones, is very long. Consequently a reply to Dubinin's article, written by D. K. Beliaev, was not published in *Priroda* until a year later. Beliaev, who in 1976 had already been appointed President of the 1978 International Genetic Congress in Moscow, was reluctant to acknowledge the seriousness of the controversy among the Soviet geneticists. He clearly explained, however, that he disagreed with Dubinin's simplistic explanations. Behaviour, he wrote, as well as many of man's intellectual abilities, certainly depend on social factors, teaching and training, but these factors act on a highly differentiated population and the main organ of mental activity—

the human brain—is not excluded from genetic laws and genetic diversity.

Dubinin published a new detailed article on the subject which appeared earlier this year in *Voprosy Filosofii*. It mostly repeated his earlier arguments, though it was more politicised. The ideas about the intellectual or spiritual aspects of human life became rather mystical, in spite of regular quotations from Marx, Engels and Lenin.

Through a complex of pseudo-scientific argumentation, Dubinin tried to state that the intellectual and ethical progress of *Homo sapiens humanis* is properly directed in one social system only. In any other social system there is no progressive evolution. Social systems create the real man after birth; the priority of genes before birth is not questioned. Good systems create good persons, bad create bad. From Dubinin's autobiography it is clear that he considers himself a good man whose psychology and intellect has been developed under the influence of the best social systems. "I am thankful for my fate . . . I do not want to live another life . . . " He is happy. During his 70 years of life, he never discovered that 30 years of Stalinist terror were not good for the creation of *Homo sapiens humanis.*

There is, however, at least one important factor for securing the happiness of *Homo sapiens logic*—freedom to do research, whether genetic, social or political. Using his position as the director of the main Institute of General Genetics, his influence as Consultant on Biology for the Central Party Committee and his membership of different commissions and groups, Dubinin is working hard to suppress by all possible means the development of genuine research in the field of human genetics in the USSR. Even now the Soviet Union is not involved in many important fields of research in human genetics. As part of medical science, human genetics now has modest conditions for research into several specially selected problems, mainly associated with health programmes. But as a part of general biology, evolution research or population genetics, human genetics does not really exist in the USSR.

In a great country with more than a hundred national minorities, several different races and many different cultural roots, human genetics is probably too hot a science to handle. ☐

ILL at ease

Judy Redfearn finds out about neutron research at the Institut Laue-Langevin and talks to its director

NEUTRONS have long been recognised as valuable tools for research. Their importance is still growing as new techniques are enabling them to find new applications in different branches of science. One of the world centres for neutron research is the Institut Max von Laue-Paul Langevin (ILL) in Grenoble, France. It is jointly run by Britain, France and Germany, and this year, when it celebrates its tenth anniversary, has seen the appointment of a British scientist as its director.

He is Dr John White, a physical chemist from St John's College, Oxford, who took over from Professor R. Mössbauer, a German, last March. He faced a pressing problem after he took up his new post: what to do with spent fuel rods from the high flux reactor, the cornerstone of ILL's neutron facility. ILL has been assured of a fuel supply since President Carter lifted his ban on the export of enriched uranium, but the freeze on reprocessing caused some worries. Just last week, however, it was granted a licence to import 12 fuel elements into the USA for reprocessing at ERDA's Savannah River plant in Georgia.

But President Carter's policy is not the only factor which may influence ILL's future. The lifetime of the high flux reactor and the value of all ILL's facilities to its member states are now being assessed to determine the institute's long term prospects after 1982, the earliest date at which the three member countries could, under the original agreement, revoke their commitment. An extensive study of the reactor has shown that it may yet have 20–25 years more life in it—"a tribute", says Dr White, "to the French and German engineers who built it". If further studies support this, a report on the institute's future, due in the autumn, should give a firm assurance that the reactor will continue operating into the 1980s.

How it will continue, however, is not yet certain. The report is expected to recommend whether or not it should go into a 'deuxième souffle'—a second stage involving the member states in another major investment to extend the facility's scope. Dr White believes that ILL will only survive into the 1980s if instruments and techniques are constantly up-dated. "At the moment we have got world leadership in this area —and we have got to keep it up."

A matter of satisfaction

ILL's future success will depend, as it always has, on how well it satisfies its visiting researchers. Unlike many other laboratories and research organisations, it is essentially a users' laboratory. Some 70% of the neutron-beam time is available for outside experiments, mainly from universities and institutes in the three member countries but also from many other parts of the world. Only 400 staff, of which 70 are PhD scientists, are employed under five-year contracts to keep instruments running. ILL's Scientific Council considers approximately 700 experimental proposals each year; at its last meeting in March, it reported requests for twice as much experimental time as is available.

Experiments originating in the member countries are funded by the organisations, or Associates, which run the institute: the Science Research Council in Britain, the Gesellschaft für Kernforschung in West Germany, and the Commissariat à l'Energie Atomique and the Centre National de la Recherche Scientifique in France. France and Germany signed the first intergovernmental treaty giving the go-ahead for the building of ILL in 1967. It was not until 1973 that Britain, having abandoned an idea to build its own intense neutron source, joined in, paying a share of the original capital investment. Routine operation of the high flux reactor, which cost FF240 million of the FF335 million spent on building the whole institute, began in 1972. It has almost completed five years of successful operation and most of the instruments designed around it

ILL

ILL's director, John White

have now been working for 2½ years.

The high flux reactor is possibly the most intense continuous neutron source in the world at the moment. It operates at 57 MW and contains a single fuel element of 9 g of 90% enriched uranium. Because such highly enriched uranium is contained within a small reactor core, the fission process is concentrated into a small volume and the resulting neutron radiation is very intense.

"If the first unique feature of this reactor is its high flux density", says Dr White, "the second is the interesting and varied sources of neutrons which surround the core". Neutrons straight from the reactor are all slowed down to thermal velocities as they pass through a vessel of deuterium at 300 K. Those emerging from a particular part of the reactor are then speeded up by a piece of hot graphite to form a hot source. Other neutrons pass through liquid deuterium at 25 K and are slowed down even further to form a cold source. But perhaps the most important feature of ILL's reactor is the great increase in experimental area created by conducting some of the thermal and cold neutrons through special conducting pipes away from the space surrounding the reactor, which is crowded with instruments.

It is the ways in which they interact with matter that have made neutrons valuable research tools. Four properties make slow neutrons particularly useful in the study of liquids and solids: their electrical neutrality, short wavelength, low energy and magnetic moment. Because they have no electric charge they can penetrate the atom's electron shell and interact with the nucleus. Their short wavelength—of the same order as the atomic diameter—means that they are scattered by a regular array of atoms in a crystal to form a neutron diffraction pattern. Their low energy—of the same order as the quanta of vibrational energy of the scattering sample—means the dynamics of solids and liquids can be studied by measuring speed changes in the scattered neutrons. So called magnetic scattering occurs when the magnetic moment of the neutron interacts with an atom's magnetic moment; it facilitates the study of the magnetic properties of solids and liquids.

ILL's high flux reactor: view from the top

ILL

Diversification

Physicists were aware of the value of the neutron's properties 20 years ago when they started using them for studies in solid state physics. But it is only over the past ten years that they have been used in chemistry; and in the past three to four years they have found applications in biology as well—last year saw the first international conference on neutrons in biology. Dr White says that ILL's curious instrumentation has helped it to make a unique contribution in some of the new areas of science, particularly in polymer chemistry, biology and nuclear physics. The structure of biological materials, for example, can often be revealed in the diffraction patterns of neutrons scattered from them.

The phenomenon which makes neutrons so potentially valuable in chemistry and biology is called 'contrast'. It can best be explained by analogy with light. A glass rod immersed in a liquid will be clearly visible provided that the refractive index of the glass differs from that of the liquid. If the liquid's refractive index is changed to be the same as that of the glass, the rod will seem to disappear. Similarly, a biological material can be immersed in a mixture of heavy and light water whose refractive index with respect to neutrons is the same as parts of the material. Those parts of the material will then make no contribution to the neutron diffraction pattern and will have been 'contrasted' out. This means, for example, that a neutron diffraction pattern could be formed from, say, the RNA molecules inside a virus, no contribution to the pattern being made by any other part of the virus.

Dr White believes that the recent branching out into broader areas of science has come from a happy interaction between the interest of the users of ILL and the instrumentation that was already there. Britain added to the creative atmosphere by bringing many problems to be solved; the French and German approach had always been to design instruments to find new ways of working with neutrons. The two approaches combined well to bring forward an expansion in the use of neutrons for research. As Dr White puts it, "The French are a bit Cartesian, they tend to think mathematically; the Germans are Leibnitzian; and the British tend to be empirical". But he does feel that ILL gains rather than suffers from the fusion of these three different scientific temperaments.

The institute is assured of a supply of fresh ideas not only because so many different nationalities work together, but also because there is a regular turnover of permanent staff. Although the average age of the staff, 34, means that ILL is a place for young people with good ideas, it does have one disadvantage. Each year the 2½–3% net growth in ILL's budget allowed for by the Associates is gobbled up as the predominantely young staff moves up the salary scale, leaving very little for building new instruments.

"At the moment we are only building one or so instruments a year, which is hopeless because the normal amortisation rate for such heavily used instruments as those at ILL is 10 years at the most. At the present rate of building, instruments will be 15 years old or more before they can be replaced". Somehow, ILL is hoping to find a way of subsidising its budget so that more instruments can be built.

Move under way

A move in this direction is already under way. Since March, Dr White's main scientific concern has been in establishing a source of ultra-cold neutrons which are just energetic enough to reach a height of 15 feet in the earth's gravitational field. They are totally internally reflected from quite common materials and so can easily be trapped for experimentation.

Perhaps the most exciting application they could have is in the field of neutron optics. Existing techniques for focusing neutrons, for example, are as crude as the techniques used by Newton 300 years ago to focus light. As yet there is no neutron lens but the ultra cold neutrons travel so slowly that they can be focused with a magnetic field and could be used to develop neutron-focusing techniques. Already a highly coherent neutron beam has been produced at ILL. It is by no means a neutron laser, but it does have some of a laser's properties which could be useful in neutron optic studies.

"The people who come to ILL have got particular problems that can be solved no other way than by neutrons", says Dr White. "Even five years ago, we wouldn't have believed that neutrons would have the sensitivity to detect the things they now do; but with the high flux and the specialised instruments at Grenoble, we have seen hitherto unobservable things". When the spallation neutron source—a pulsed source of very hot neutrons just approved in Britain—is built at the UK's Rutherford Laboratory, he claims that Europe will house the world's most sophisticated neutron facilities. □

Assessing the 'greenhouse effect'

A report on the climatic effects of energy consumption was made public last week. Colin Norman reports from Washington

If the world's burgeoning demand for energy is met by burning increasing amounts of fossil fuels, there could be significant changes in the Earth's climate, lasting at least a millennium, a committee of the National Academy of Sciences warned in a report made public last week. Though the report is hedged with uncertainties and qualifications, the committee reckons that if the use of fossil fuels continues to increase at present rates, average global temperature could rise by about 6°C over the next 200 years, with potentially dire consequences for agriculture and fisheries.

The report, prepared by a committee headed by Roger Revelle, a noted ecologist who holds joint appointments at Harvard and the University of California, constitutes the first major attempt to assess the validity and potential consequences of the so-called "greenhouse effect", which may result from loading the atmosphere with carbon dioxide by burning coal, oil and gas. The theory is that carbon dioxide in the atmosphere will absorb heat radiated from the Earth's surface, causing an increase in global temperature, which in turn could trigger a variety of climatic changes.

The greenhouse effect was first postulated several years ago, but the theory has been controversial and the magnitude of its potential impact has been the subject of considerable debate. The Academy committee acknowledges that the data supporting the theory are incomplete, but the evidence is nevertheless strong and "the implications warrant prompt attention". Though the committee looked into other potential climatic impacts of energy use, such as the direct addition of heat to the environment and increasing the amount of particulates spewed into the atmosphere, it found that the carbon dioxide effect is likely to be far the most significant and it "may be the primary limiting factor on energy production from fossil fuels over the next few centuries".

On the basis of a number of climatic models and several years of direct measurements, the committee calculates that the concentration of carbon dioxide in the atmosphere has increased by between 11% and 13% from the beginning of the industrial revolution to the present. It may increase by 25% by the turn of the century, double by the year 2050 and reach between four and eight times its pre-industrial level in 200 years' time, if use of fossil fuels continues to grow.

The effect of such a rise in carbon dioxide concentration would be a 6 °C increase in average global temperature over the next 200 years and temperatures at the poles would be expected to increase even more, the committee states. In addition, precipitation is likely to increase and there could be severe regional changes in weather patterns.

It is important, however, to note the basis for those predictions first, the projected increase in carbon dioxide concentration is based on the assumption that use of fossil fuels will continue to grow as the industrialised countries switch from oil and gas to coal to meet their energy needs. Another key assumption is that per capita energy consumption will increase and that population will rise to a level of 10 billion toward the end of the twenty-first century. Those projections could be greatly affected by policies to curb the environmental impact of strip mining, by deliberate attempts to convert to other energy sources, by efforts to curb energy demand, and by policies to restrict population growth. The report's conclusions are therefore essentially based on an extension of present trends.

The projections are, however, founded on some key measurements of carbon dioxide concentrations at sites in Hawaii and the South Pole over an 18-year period during the 1960s and early 1970s. The measurements, made by Charles D. Keeling of the University of California at San Diego, are the first positive confirmation that carbon dioxide levels are increasing. They indicate that carbon dioxide concentration increased by about 5% over the period, and they suggest that about 40% of the carbon dioxide released into the atmosphere had remained there. The committee concludes that about 40% of the carbon dioxide released during that period was taken up by the terrestrial biosphere and the remaining 20% was taken up by the oceans. The projections of a doubling of carbon dioxide concentration over the next century and a four-to-eight fold increase by the year 2050 are essentially an extension of those calculations and measurements.

The link between increasing carbon dioxide concentrations and increasing global temperature is based on a computer model of the Earth's climate which the committee acknowledges is "imperfect in a number of significant ways" but is "the most complete yet devised". The model predicts a 3 °C increase in the temperature of the lower atmosphere for each doubling in carbon dioxide concentration, and a

TVA appointment

President Carter last week gave a clear signal of his intention to set a new course for the giant Tennessee Valley Authority (TVA) by nominating S. David Freeman, an advocate of energy conservation and solar power, to fill a long-standing vacancy on TVA's board of directors. Freeman, who first came to prominence when he directed the Ford Foundation's multi-million dollar Energy Policy Project, is also expected to become chairman of the three-member board when the present incumbent, Aubrey Wagner, retires next year.

Established in the Great Depression as part of Franklin Roosevelt's New Deal, TVA has developed into the largest electric utility in the United States, serving an area the size of Great Britain. It was created primarily to raise the economic level of one of the poorest regions in the United States, but energy supplies dominated operations. It is the largest single purchaser of strip-mined coal, and has had a bitter battle with the Environmental Protection Agency over its policy of dispersing pollutants from its power plants through tall smokestacks. TVA has also embarked on a massive nuclear programme, with plans to have as many as 17 nuclear reactors in operation by the mid-1980s.

Critics have contended that TVA's poor environmental record, and its relative neglect of alternative sources of energy, are a far cry from its original goal. Carter has echoed such complaints. Now he has indicated that he would like the authority to recapture some of the innovative spirit which predominated during its early years. Freeman is at present an assistant to James Schlesinger, Carter's chief energy adviser.

Colin Norman

7% rise in average precipitation.

The effects of such an increase in temperature could be serious. The committee notes that there would be a poleward shift in the world's agricultural zones, marked changes in the location and extent of arid and semiarid zones, and potentially serious changes in regions of precipitation. For the north American breadbasket, for example, the effect could be to push the corn belt northwards off the productive soils of the midwest and on to poorer Canadian soils. The impact on the oceans could be even more severe. A warming of the surface layers could be expected, which would reduce vertical circulation, thereby reducing the biological productivity of the oceans because it would depress the circulation of nutrients. There would also be a significant shift in the location of the major fisheries.

A five-degree warming of the upper 1,000 m of ocean water would also raise the ocean level by simple expansion by about 1 m. Melting of sea ice would augment the rise in ocean level. As for the potential impact on the polar ice caps, the committee states that "in the present state of understanding, it is impossible to forecast what might happen to the Greenland and Antarctic ice caps". Since temperatures over the ice caps would be expected to remain below the freezing point, however, "melting at or near the surface of the ice probably would not occur". But increased precipitation associated with increased levels of carbon dioxide could lead to substantial increase in ice thickness, which in turn could cause severe stresses at the base of the ice caps and surges and slides of ice into the sea. "If these surges resulted in destruction of the west Antarctic ice cap, there might be a corresponding rise in sea level of about 5 m within 300 years", the committee notes.

The report does not consider in detail the potential impact of global warming on regional weather patterns, climatic variability and shifts in ocean currents because of the difficulty predicting such effects.

The committee's chief recommendation is that a major research effort should be instituted, on a worldwide basis, to address some of the major unknowns in the climatic models and measurements on which the projections are based. Such an effort could cost between $20 and $100 million a year, Revelle suggested last week.

The report's chief impact, however, is likely to be on discussions of energy policy. The committee notes that if the potential for climatic change is substantiated, it may be necessary to reverse the trend of consumption of fossil fuels. The committee adds: "In the face of so much uncertainty regarding climatic change, it may be argued that the wisest attitude would be laissez faire. Unfortunately, it will take a millennium for the effects of a century of fossil fuels to dissipate. If the decision is postponed until the impact of man-made climate changes has been felt, then, for all practical purposes, the die will already have been cast". ☐

Jupiter success

THANKS to an intense lobbying effort by space scientists, university administrators and Governor Jerry Brown of California, the Jupiter Orbiter Probe, a key space science project, has survived a strong challenge in Congress. The House of Representatives last week rejected a recommendation from its powerful appropriations committee that the project should be killed, and voted funds to begin building the spacecraft next year. Since the Senate had already approved the project, the House vote constitutes the final go-ahead.

The Congressional debate over the Jupiter project provides an object lesson in the politics of big science. It also demonstrates the power that the scientific community can muster when it unites behind a major project.

Long considered a top priority space science mission, the Jupiter Orbiter Probe will involve the launch in January 1982 of twin spacecraft to orbit Jupiter and send scientific instruments into the planet's atmosphere. The total cost is expected to be close to $300 million. Though the project has been on the drawing board for several years, this is the first year that the National Aeronautics and Space Administration (NASA) has asked Congress for funds to begin building hardware.

NASA officials were not anticipating much opposition to the project from Congress, and they consequently received a shock earlier this year when a House appropriations subcommittee, chaired by Edward Boland of Massachusetts, recommended that all funds for the mission be deleted from NASA's budget. The subcommittee's action, which was later upheld by the full appropriations committee and the House itself, was based on the fact that NASA was also requesting funds to begin building the Large Space Telescope. The subcommittee said that it would be willing to sanction only one major space science project, and it opted for the telescope.

Once the subcommittee's vote against the project was made known, the scientific community mobilised to reverse the decision. A flood of letters and telephone calls descended on members of the Senate appropriations committee in an attempt to persuade the Senate to keep funds for the Jupiter project in its version of the NASA budget bill. The lobbying was successful, and it was then widely expected that when differences between the House and Senate versions of the budget bill were ironed out by a House-Senate conference committee, the Jupiter project would emerge with sufficient money to meet the launch schedule. But further problems arose.

House members of the conference committee refused to compromise on the project, insisting that it must be dropped in order to provide more money for higher priority efforts. Senate conferees, similarly, insisted that the project be allowed to proceed. To break the deadlock, the matter was referred back to the House for a separate vote last week. The lobbying was at its most intense shortly before the House vote.

The Jupiter Orbiter Probe is the only planetary project up for approval, and NASA officials thus argued that if it were killed there would be a major hiatus in planetary research. Abandoning the project would result in breaking up teams of scientists and engineers who have been working on planetary programmes, and continuity from one project to another would be lost, NASA officials argued. Moreover, since there would not be another suitable launch window until 1987, denial of funds for the project this year would effectively put Jupiter out of reach for another five years.

The chief political asset for the project, however, was the fact that it will be based at the Jet Propulsion Laboratory in California, a state with a large Congressional delegation and considerable political muscle. Alarmed at the prospect of losing a $300 million federal project, Governor Brown telephoned a number of Congressmen before last week's vote and urged them to support the project. As a result, the California delegation united with other supporters of the project, and the opposition of the appropriations subcommittee was easily overcome. The vote in the end was 131 to 280.

BRITAIN

● Concorde supporters can take heart at the news that British Airways is to use the plane to fly twelve batches of generators of a newly-developed radiopharmaceutical across the Atlantic to waiting patients with lung complaints at Johns Hopkins Medical Unit, Baltimore, and the Washington Hospital Center. Doctors at Johns Hopkins took delivery of the first batch last week, and are reportedly delighted with it.

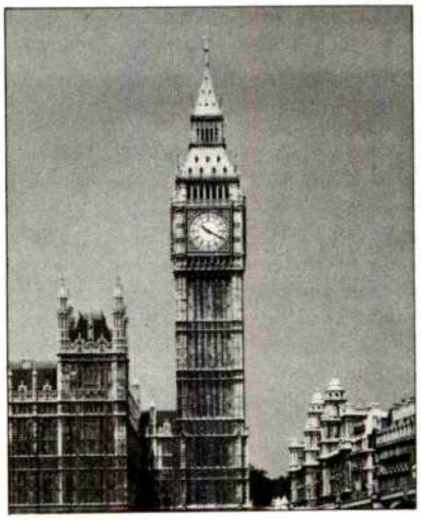
The new radiopharmaceutical, krypton-81m, helps doctors diagnose lung diseases. It was developed about two years ago by researchers at the Medical Research Council Cyclotron Unit at Hammersmith Hospital in London. It cannot be flown across the Atlantic subsonically because rubidium-81, the generator from which the krypton-81m is obtained, decays so quickly; it would be too weak to be used by the time it arrived. But Concorde cuts the transatlantic crossing time from 8 to about 3½ hours, and if twice the normal requirement of rubidium-81 is loaded onto the plane, sufficient radioactive strength remains after the journey for up to ten hours of clinical use.

It is krypton-81m's short half-life which makes it so useful. At 13 seconds, it is the shortest-lived radioisotope in medical use. The patient is positioned in front of a gamma camera and breathes in air containing a trace of the radioactive krypton which decays rapidly inside the lungs. The gamma camera records the regional arrival of air, enabling doctors to see immediately which parts of the lung are receiving no air. Previously only total lung volume could be measured, using long-lived isotopes.

At Hammersmith, krypton-81m has been used to monitor progress and response to different treatments. By itself it is not a good diagnostic technique, but in conjunction with standard perfusion techniques, which record blood supply to the lungs, it provides unique information for the diagnosis of such lung diseases as pulmonary embolism, asthma and chronic bronchitis.

● The good thing about the UK National Coal Board's (NCB) activities last year was the £27 million profit it made, said its chairman, Sir Derek Ezra, when the 1976–77 annual report was published last week. What wasn't so good, he said, was the fall in production and productivity.

This apparent paradox has arisen three years after the introduction of Plan for Coal, a scheme set up in 1974 which would allow expanded exploration and research. Sir Derek puts 1976–77's profit down to achievements under the Plan as well as increased sales, a 10% increase in open-cast mining output and economies of operation.



The most notable short-term research success was the development of the in-seam miner, which won the Queen's Award for Technological Achievement. It has mechanised some manual tasks and has improved the working of face ends and the opening of new faces. Short-to-medium term mining research programmes aim at further automation. Fluidised bed combustors to improve coal utilisation are being developed for commercial use. They are already available on a small scale, but have yet to be developed for use in power stations.

The long term hopes for achievement in coal research, however, go hand in hand with expectations for coal in meeting future energy demands. If coal is to become a more important energy source as oil supplies dry up, the NCB must increase production, find new coalfields and develop ways to convert coal to chemical feedstocks, gas and liquid fuels. Under the long term plan, Plan 2000, research aims at completely automated mining, especially of deep or remote seams inaccessible to miners. One method enjoying moderate success is the removal of coal which has first been liquidised underground, and a multidisciplinary group has explored the long term possibilities of such methods with research establishments in the UK, USA and West Germany.

All in all the NCB spent £20.8 million on research in 1976–77, about 0.7% of gross turnover. Of the different research categories—mining, utilisation, medical and others—mining received the lion's share. The trend is expected to continue this year.

● Professor Thomas Symington, director of the Institute of Cancer Research (ICR), has announced his retirement two years before it was expected. The decision was made mainly on personal grounds and its suddenness will leave the Institute temporarily without a director. Professor Leonard Lamerton of the Institute's Biophysics Department will be director for the time being until a substantive director is appointed.

The Institute of Cancer Research, consisting of the Chester Beatty Research Institute in London, the Pollards Wood Research Station at Chalfont St. Giles in Buckinghamshire and several Departments on the Sutton, Surrey, site of the Royal Marsden Hospital, has an annual budget of about £3 million: half of this comes from the Medical Research Council (MRC), £650,000 from the Cancer Research Campaign and the residue from legacies' interest and grants from overseas. The ICR has had to face a fall in the MRC's block grant and the removal of a £200,000 allocation to the animal facilities. Symington told *Nature* that this was a temporary problem and had no influence on his decision to retire.

When Symington became director seven years ago, the Institute needed reorganisation to rid itself of its less effective research staff. The MRC insisted on converting much of its funding from a block grant into support of specific programmes and projects to be accounted for on a regular basis. By most accounts the Institute under Symington came to withstand that kind of scrutiny. He leaves wishing only that he could have unified the various parts of the Institute on the campus of a medical school.

● Pro-nuclear Labour Party activists could face a problem when the party gathers in Brighton for its annual conference in the first week of October. Of nine resolutions on energy, not one has a good word for nuclear power—and not one fails to mention nuclear power. Three resolutions appear on nuclear weapons, and just one on defence generally.

BRITAIN

Awkward decision

In an embarrassing and controversial decision, the UK Medical Research Council (MRC) last week agreed to "run down" its Demyelinating Diseases Unit in Newcastle. Chris Sherwell reports

ON THE face of it, the MRC's decision is in line with its overall policy regarding research units, namely that they last as long as the directors to which they are attached. A glance at the two most recent MRC annual reports, for example, shows a sizeable turnover, with two or three units a year appearing and more disbanding. The director of the Demyelinating Diseases Unit left over a year ago. So without a new director a run down and redeployment of the unit's 33 staff, if not closure altogether, was always on the cards.

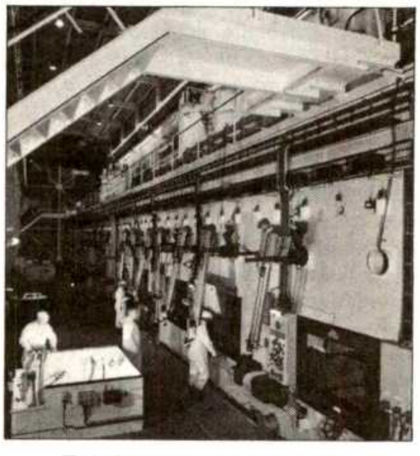
The demonstration outside MRC headquarters on the day the decision was taken, however, suggested that this particular case was different. And so it is. Partly this is because a well organised and highly unionised staff at the unit was resisting the MRC, an example of a phenomenon that the Council is only just beginning to accommodate. The more important reason is that the MRC has set such store by its multiple sclerosis (MS) research effort, of which the unit is a part. Not to be able to find a suitable director to take over the unit, which is the problem the MRC says it has faced, has made for many red faces. Some concerned lobbying from MS-related organisations has added to the controversy.

So too has the unit's stormy history, which finds its best expression in the circumstances surrounding the departure of E. L. Field as director in 1973. His controversial work is still debated, some say partly because the failed efforts to repeat his work have never been published. Henry Wisniewski became director in October 1974 but left in June last year for what were described as personal reasons. Work inspired by his animal model continues; this involves the development of a chronic relapsing form of experimental allergic encephalomyelitis which in important ways mimics MS.

Whether this would have remained a promising course of research, particularly without Wisniewski, is now a matter for speculation. But his departure brought more administrative problems, for he had been difficult to find. In an effort to keep the unit going the MRC cast round again for another director. One man who was invited declined, in spite of what the MRC calls "considerable material inducements". Several other candidates applied, including at least one from the unit itself. None fitted the bill. Advertisements which broadened the scope of the job to include dementias had not helped.

In May the MRC took a decision in principle to run the unit down. The Council met last week to consider an appeal from the staff, but the outcome was almost a foregone conclusion. The statement confirming that the decision would stand expressed great regret. A formal statement giving detailed reasons is expected this week. Whether this will try to explain how and why no director could be found to take the job is unclear. But in the meantime the MRC will probably be hoping that the unit it is now running down might one day start again. □

Material aid



Decanning Magnox fuel (BNFL)

BACKGROUNDER

"LOST!", the *Sun's* front page headline boldly proclaimed. "Enough plutonium to make fourteen A-bombs. Finder please return to Tony Benn". It was one way—a popular daily's way—of reporting what was perhaps last week's non-story in Britain. Most other papers recognised it for what it was and gave it less prominence. But they still faced the problem of explaining that there was no problem.

The occasion was the publication by the UK Atomic Energy Authority (UKAEA) and British Nuclear Fuels Ltd (BNFL) of data on nuclear materials accounting in Britain. The figures seemed to show that, since 1970, 96.8 kg of plutonium had gone "missing" from Windscale and 97.6 kg of highly enriched uranium from Dounreay. These are the sums of annual inventory differences—of arithmetical differences between the physical inventory and the book inventory of nuclear materials coming into, moving through and leaving any particular site or part of a site.

The annual inventory difference is known as MUF—material unaccounted for. And it is never zero. In these nuclear-fuel fearing days, the idea that plutonium or enriched uranium cannot be accounted for is, well, explosive. After all, if material always *seems* to be missing, how is anyone to know when it really is missing? But it does not always seem to be missing; sometimes it seems to be growing. And for the same reasons that the UKAEA and BNFL are sure that no one has given them material illicitly, they are sure no one has taken it either. Those reasons are to be found in the security measures they adopt, of which MUF is simply not an integral part.

So what is MUF? Essentially it is a recognition of the need to account for valuable materials—a need admittedly highlighted by the first reports three months ago that a shipload of uranium disappeared in 1968 between Antwerp and Genoa and by demands from such groups as Friends of the Earth for details of nuclear materials accounting in Britain and elsewhere. But accounting has always been there; and the techniques are apparently improving. What is new are the figures themselves.

In Britain the accounting balances are struck on a quarterly or monthly basis. Their minimal value as an aid against diversion might improve if, as is said to happen at some US plants, a balance is struck once a shift. But the MUF concept was not designed for this purpose.

The figures will move closer to zero only as built-in sources of error are reduced. These include inaccuracies in, for example, estimating the amounts of plutonium in irradiated fuel elements. Estimates of plutonium at other stages are also fraught with difficulty. No one is expecting the figures to reach zero.

MUF figures justify few fears or hopes. But if the accounting wasn't there, it would have to be invented; and most people would rather have the figures calculated.

IN BRIEF

R & D statistics

Total expenditure on R & D at colleges and universities in the United States increased by 9% last year, about 2% above the rate of inflation, according to a series of figures released last week by the National Science Foundation. Within the total, however, spending on basic research rose by only 5%, less than the rate of inflation, while support for applied research rose faster than inflation.

The overall proportion of R&D funds in universities and colleges devoted to basic research has declined from 77% in 1970, to about 68% this year, the figures suggest. Earlier this year, a study of the health of academic science indicated that declining support for basic research has seriously eroded the quality of research in some institutions.

MAFF's chief scientist

After five years as Chief Scientist at the UK Ministry of Agriculture, Fisheries and Food, Sir Charles Pereira will be retiring at the end of November. Professor B. G. F. Weitz, Director of the National Institute for Research in Dairying at the University of Reading, will succeed him. Professor Weitz will inherit responsibility for identifying R & D needs and for the department as a 'customer' under the customer/contractor arrangements for applied research. He will also have £42 million at his disposal for R&D in 1977–78.

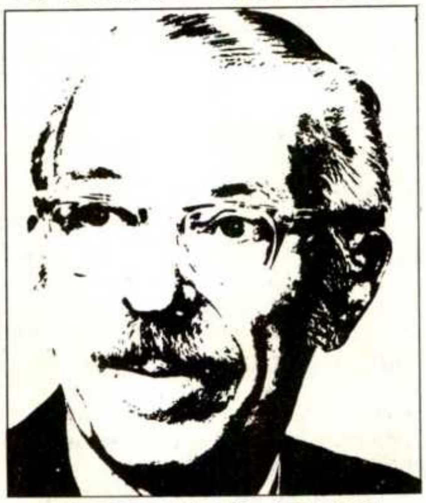
Professor Weitz's research interests have included the development of Brucella vaccines, the action of tetanus and diptheria antitoxins and the immunological aspects of tropical diseases transmitted by insect vectors.

CERN's saving

Figures which emerged at the June session of the CERN Council in Geneva confirmed a SF50.1 million saving (at 1970 prices) on the super proton synchrotron (SPS) programme that will end in 1979. The SPS programme is now estimated at SF1,099.9 million. The Council also agreed to prolong until August 1980 the agreement CERN has with the European Southern Observatory; the 1978 budget for this is estimated at SF618.7 million.

From the beginning of next year the new leader of CERN's experimental physics division will be Dr Erwin Gabathuler (43), from Britain. He has been project leader, European muon collaboration, since 1974. Before that he was responsible for the Daresbury-based programme at CERN.

COSPAR in Israel



THOMAS H. JUKES

ACRONYMS are a modern nuisance, but all of us make use of them to some extent. COSPAR means the Committee on Space Research of the International Council of Scientific Unions, and this mouthful refers to an international scientific organisation concerned with fundamental research carried out with the use of rocket-propelled vehicles. COSPAR functions as a sort of scientific mini-UN, and holds annual meetings in various member countries. This year, after considerable behind-the-scenes give-and-take with the Soviets, the invitation of Israel as host had finally been accepted. There were symposia on instruments for space astronomy, on travelling interplanetary phenomena, on Viking experiments and on global food information systems. There were also, as usual, meetings of various 'working groups', all of which are recorded in the Book of Chronicles of the Goings-on in Israel (also known as the abstracts and proceedings of the twentieth COSPAR meeting).

I have been regaled many times with accounts of visits to the Holy Land, starting with Mark Twain's *Innocents Abroad*, but I found that to see Israel for the first time is a deeply cultural and emotional experience. The land stands once more at the pinnacle of a climactic episode of her history. Who can deny that the rest of the world owes something to the Jews, the Israelis, in the light of what has happened in the past 50 years? But how can I phrase these ideas adequately? I am subdued before the oratory of the great, spanning the millennia, from Elijah to Abba Eban, and by the words of the Irishman who reminded us that the tables of the Law were graven in the language of the outlaw.

I must urge you to visit the museum of Yad Vashem in Jerusalem. We approached it through a small avenue of trees, each of which is dedicated to a Gentile who helped the Jews during the era of the Nazi holocaust. After the fire comes a still, small voice. Replicas of the Yad Vashem museum should be built throughout the world, especially in the Soviet Union, so that all may see its contents, which vividly depict what happened in Germany and in the countries occupied by Hitler, 1939–1945.

The Dead Sea is a grand object-lesson in comparative toxicity; useful in discussions of the subject with consumers who are nervous about poisons in their food. Drinking moderate quantities of Dead Sea water is fatal, because of its high content of magnesium (14%), sodium (7%), and potassium (4%) chlorides. A drop splashed in the eye causes intense pain. Yet these salts, in lower concentrations, are essential to life. The most crucial activity of all cells, protein synthesis, depends on ribosomes, and these need magnesium ions to maintain their integrity and function. Neither can we exist without sodium, postassium and chloride ions.

The contrasts in Israel are startling. We drove, on a modern highway, out of a brand-new town with sprinklers watering the flowering oleander bushes. Soon we were in barren, rolling country where Bedouin Arabs herded goats beside tents whose design had not changed for centuries, camels who sniffed the evening, and donkeys who serenaded it under high-tension power lines. Back to the coast we rolled through the ancient city of Jaffa, and to the new University of Tel Aviv for an outdoor evening reception. Here a professor introduced the dean, in a short speech that included a gentle reminder of budgetary needs for his department. The dean, after the manner of his kind, welcomed us warmly, but made no promises about the budget. We drank the wine, labelled 'Product of Israel, Cabernet Sauvignon'. It was just like California, where most red wines seem to be labelled 'Cabernet Sauvignon'. Vive la France, vive le COSPAR!

correspondence

Torture

SIR,—In June, Amnesty International published a monograph containing the results of three research studies conducted by its Danish Medical Group[1]. The studies concerned modern methods of torture. This group, which came into being in October 1974, is the first of its kind, and its pioneer work will serve as a pattern for similar groups in other countries.

One of the reasons that this group was formed was the disclosure that in certain countries doctors have cooperated in inventing new, sophisticated ways of torture that can be used without leaving any visible evidence. To be able to prove that such methods have been used, medical experts are needed. Ingenuity in this field seems to be unlimited, but with every new revelation of torture methods, one can only hope that public opinion will have a preventative or at least restraining effect on those using them.

Thanks to the initiative of the Danish doctors, Amnesty International will form a 'Medical Advisory Board' which will encourage the forming of research and action groups in other countries and coordinate their work. Such groups have come into existence in the USA, Sweden, Holland and within the near future there may be a similar group in Britain.

Forming research and action groups is one way of helping to implement the 1975 declaration against torture that was accepted in Tokyo by the WMA General Assembly. In this declaration doctors are admonished to abstain from participating in any physical or psychological torture of prisoners. The 'Declaration of Tokyo' is an important document in a time when torture unfortunately is a matter of common occurrence in a number of countries in different parts of the world.

A doctor must refuse to participate in torturing a prisoner, but should he not also actively oppose torture? The Amnesty groups of doctors are of that opinion. As an example of what official medical organisations can do, the Swedish Medical Association has faced the question of acting on behalf of individuals or minorities that have been subjected to political persecution, torture and other inhuman treatment. As a rule, Amnesty International has initiated these actions, but the association has also been approached independently by its members.

Naturally, the possibilities for a medical association to have any real influence are very limited. In cases where the documentation is good, however, it has been our experience that protests to respective heads of state or other appropriate authorities can benefit prisoners and give positive results.

A combination derivation of the proton–electron mass ratio

SIR,—Atkin[1], Bastin[2] and Kilmister[3] have recently shown that a discrete algebraic theory readily generates the structures and cardinalities of the kind contemplated by Eddington[4]. In particular, Kilmister has pointed out that algebraic structures having 10 and 136 components are inevitably perpetuated by such a combinatorial approach.

It is well known that Eddington attempted to use these two numbers to account for the proton–electron mass ratio. He proposed that this ratio be identified with the ratio of the roots of the quadratic equation.

$$10m^2-136m+1 = 0 \qquad (1)$$

This quadratic root ratio is 1847.6 and was an adequate fit to the known experimental data for determining the proton–electron mass ratio in 1933, when this proposal was first made. When it became clear, however, that the experimental ratio was close to 1836, Eddington, with rather intricate physical justification, added factors to his original equation to approximate the new result. This procedure has rightly been criticised. As Kilmister puts it: "This is almost certainly the wrong way to go about things. We ought to realise that if we have any tenable theory at all on this point, we have one that agrees approximately with the results. In order to obtain better agreement, we need to recast the whole theory, not to patch it up by multiplications by constants whose values differ very little from unity".

Actually, Eddington could have recast his theory by dispensing with his notorious quadratic altogether. He had to do something physically plausible with the key cardinal numbers 10 and 136 to derive 1836. From a combinatorial point of view (with one eye open to the physics) the most straightforward procedure is the following:

if we have 136 things to choose from and need to choose 2 at a time (one for the proton, one for the electron presumably) we will have (136)(135) = 18360 ways of choosing. If we then have to distribute these ways of choosing into 10 parts (for the 10 gravitational potentials perhaps) we end up with the desired number

$$P_2^{136}/10 = 1836. \qquad (2)$$

This is close enough to the observed ratio of 1836.109 to suggest something stronger than mere coincidence.

Proposed terminology

SIR,—George S. Kell (23 June, page 665), is to be congratulated and applauded for inviting discussion of his proposed new terminology rather than incorporating it willy-nilly in a scientific paper. If other scientists had been as modest and careful then I doubt if the jargon would have been saddled with misleading terms like charm and colour. I, for one, am not charmed by the strangeness of the particle physicist's use of colour but I am sure that many viewers of a recent BBC science programme actually believe that quarks come in pretty shades of red and green. They have colour have they not? Physicists who indulge in purloining common adjectives to describe properties which bear no relation to the original meaning of the words should pause, reflect and be glad that at some time past they had not labelled some property 'gay', as in gay particle physicist.

George Kell has made a good try at avoiding such whimsy but should glance at a dictionary of geology where he will find 'psammitic' already in use, thereby pre-empting the root of his proposed terminology.

The Twin Paradox revisited

from Tom Wilkie

THE muon may be a curious particle, but the study of its properties is a fruitful one (see *Nature* **267**, 582; 1977). The accurate determination of the muon lifetime, reported in this issue (page 301), has also provided a stringent check on Einstein's Theory of Special Relativity. As an added bonus, it sheds light on the 'Twin Paradox', gives an upper limit to the granularity of space-time, and tests CPT invariance of the weak interaction. The precision of the experiment is to within 0.1%, presently the most accurate test of Special Relativity using elementary particles. It was carried out using the CERN Muon Storage Ring which was built to measure the anomalous magnetic moment of the muon and so test Quantum Electrodynamics (QED). The present experiment is doubly welcome, in that it continues the desirable trend for elementary particle experiments of very high precision, and in that it makes good use of already existing apparatus. Too often in the past, particle physicists have been content only with gross trends in their data; too often also, there have been demands for very expensive equipment to perform a single experiment. In the autumn the Ring will be adapted to accelerator physics, and will start a new life investigating the exciting field of stochastic and electron 'cooling' of proton beams (*Particle Accelerators* 7(4); 1976).

As a species of massive electron, the muon is a charged particle with intrinsic spin $\frac{1}{2}\hbar$; it therefore has a magnetic moment when placed in an external magnetic field. It is unstable; in the laboratory it decays into an electron and two neutrinos, in approximately 2.2 μs. Recently, however, there has been intense theoretical speculation that, within the context of non-abelian gauge theories, the muon may decay directly into an electron and a photon (thus violating muon conservation number). These suggestions (*Phys. Lett.* **67B**, 303 & 309; 1977) have not yet been verified experimentally. The conventional muon decay pattern has a characteristic 'sickle' shape corresponding to

$$\begin{array}{l} \pi^- \rightarrow \mu^- + \bar{\nu}_\mu \\ \quad \hookrightarrow e^- + \nu_\mu + \bar{\nu}_e \end{array}$$

This distinctive pattern is seen when the pions are stopped in a bubble-chamber, and allowed to decay at rest. In the CERN experiments, however, the pions are injected into a 14-m diameter storage ring, and allowed to decay in flight. Because this decay violates parity, the produced muons are spin-polarised and their observed decay products, the electrons, are emitted along the direction of the muon spin. It is this ability to measure the muon spin direction which allows an accurate value of the anomalous magnetic moment to be found. The theory of QED, which essentially marries Quantum Mechanics and Special Relativity, predicts certain corrections to the naive, non-realistic value of the magnetic moment. The beautiful experiment done at CERN gave a triumphant measure of these corrections (Bailey *Phys. Lett.* **68B**, 191; 1977)

$$a_\mu\ (\text{expt.}) = (1{,}165{,}922 \pm 9)\times 10^{-9}$$

$$a_\mu\ (\text{theory}) = (1{,}165{,}921 \pm 10)\times 10^{-9}$$

Although this result may be considered a very complete confirmation of QED as the most accurate physical theory ever devised, it is at best an indirect test of Special Relativity. Because the muon is unstable it can be regarded as a subnuclear 'clock', and used to measure the time dilation effect predicted by Einstein. If two identical clocks are in uniform relative motion and an observer, considering his clock as stationary, compares the time measured by the two clocks, he will see the 'moving' clock losing time as it recedes from him. However, an observer with the 'moving' clock will consider himself to be stationary, and observe the first one to be going slow. This time dilation has aroused some passion (*Nature* **255**, 519; 1975). The so-called 'Twin' or 'Clock Paradox' arises when the 'moving' clock is later returned to the stationary one; it is indeed seen to have measured a smaller time-interval. But why could we not have regarded the 'moving' clock as stationary, and expected the first observer to have aged less? The resolution is that the 'moving' system has to change its velocity (that is, undergo acceleration) to return to the stationary one; the two are not equivalent, inertial frames in the sense of Special Relativity.

The existence of cosmic-ray muons at ground level supports the idea of time dilation; for, if the muons' lifetime is not lengthened during flight, they would all decay in the upper atmosphere. There have been more precise experiments using the line-of-flight decay of accelerator-produced pions and kaons (*Nucl. Phys.* **48B**, 343; 1972; *Phys. Rev. Lett.* **34**, 1244; 1975). The advent of high-precision caesium atomic clocks has made the macroscopic test of time dilation possible. Hafele and Keating (*Science* **177**, 166; 1972) simply loaded such a clock on to a commercial jet airliner on a round-the-world trip! Although reporting a positive effect, the experimental errors were substantial.

A different approach (*Phys. Rev. Lett.* **4**, 165; 1960) uses the Mössbauer effect to examine the 'Twin Paradox'. Photons from ^{57}Fe decay at the centre of a rotor enter a resonant absorber on the perimeter, and so are prevented from registering in an external, stationary counter. When the rotor is spun rapidly, the count rate goes up as the moving absorber is no longer in resonance with the stationary emitter—its time has been dilated.

Similarly, the muons circling in the CERN storage ring at 99.94% of the speed of light closely fulfil the role of moving clocks. To move in a circle they must undergo a centripetal acceleration, that is, they are in a non-inertial frame, and so they mimic the moving twin. We would expect the CERN muons to remain younger than their stay-at-home brethren. It is indeed observed that the moving muons live longer in agreement, to one part in 10^3, with the predictions of Special Relativity. The stationary twin's time-scale is given by observation of

---

Tom Wilkie is in the Department of Theoretical Physics, University of Durham.

muonium decay (*Sov. Phys. JETP* **40**, 811; 1974).

One of our basic theoretical assumptions is that of CPT invariance: the physical properties of particles and anti-particles should be identical, apart from their charge. It is reassuring that the CERN group should have accurately verified this also.

But one of the most interesting consequences of this experiment straddles both Special and General Relativity. Any test of Special Relativity is, ultimately, a test of the homogeneity of space-time. Is it possible that space itself is quantised; that there is a fundamental distance below which we cannot probe? There has been some theoretical speculation that the existence of miniature black holes would entail such a fundamental distance. The CERN experiment puts an unambiguous upper limit ($\sim10^{-15}$cm) on the granularity of space-time. In so doing, it places a lower limit on the mass of any black hole. □

Atmospheric carbon dioxide and forest clearance

from Peter D. Moore

THE build up of carbon dioxide in the atmosphere is now firmly established, although its consequences are still a matter for debate. The frequently quoted figures from Mauna Loa in Hawaii demonstrate a rise in atmospheric CO_2 from levels of 313 p.p.m. in 1958 to 327 p.p.m. in 1975. It is generally accepted that the bulk of this rise is due to the injection of CO_2 into the atmosphere as a consequence of the burning of fossil fuels. It is also likely that the oxidation of carbon contained in living (mainly plant) biomass and in soil organic matter and litter has contributed to the rise. Farmer and Baxter (*Nature* **247,** 273; 1974) for example, have published data which implies a considerable increase in atmospheric CO_2, perhaps as much as 20 p.p.m., during the first two decades of this century, and they considered that this could be accounted for by the oxidation of non-fossil organic carbon.

On the other hand, one might expect the raised atmospheric levels of CO_2 to result in a higher gross production on the part of photosynthetic plants. CO_2 is the limiting factor for rates of photosynthesis and raised CO_2 levels are widely used to enhance the growth of greenhouse crops. It is not unreasonable to hope, therefore, that global carbon fixation is increasing as a function of CO_2 concentration. Such an hypothesis is difficult to test, however. Hall, Ekdahl and Wartenberg (*Nature* **255,** 136; 1975) attempted an analysis of the Mauna Loa data which was designed to isolate CO_2 fluctuations due to changes in the biospheric reservoir of carbon. They estimated the month-by-month variation in CO_2 output by industry in the Northern Hemisphere and used the curves produced to correct the ambient CO_2 record over the period 1958–1972. Making allowance for oceanic uptake (estimated at 42%) they could then obtain values for the overall photosynthetic and respiration of the biosphere by comparing the differences between the succeeding seasonal peaks and troughs in the atmospheric CO_2 concentration. Their conclusion was that there had been no basic change in the pattern of biosphere metabolism. An alternative way of interpreting their data would be to postulate that any increase in production has been matched by an increase in respiration, or its chemical equivalent, biomass oxidation by combustion.

Bolin (*Science* **196,** 613; 1977) has recently discussed the influence of changes in land biota on the carbon cycle and he also emphasises the influence of forest clearance and agricultural development on the atmospheric carbon load. According to his calculations the atmosphere contains about 690×10^9 tons of carbon (327 p.p.m.). Over the last decade the input from fossil fuel combustion has averaged 4.0×10^9 ton yr^{-1}, but at the same time there have been changes in the biosphere which will also have led to a net input of carbon to the atmosphere. Bolin estimates these rates at: deforestation and fuel wood production, 1.1×10^9 ton yr^{-1}; changes in organic matter in the soil, 0.3×10^9; less the drain on the atmospheric carbon level resulting from reforestation, estimated at 0.3×10^9. Thus the overall net injection of carbon into the atmosphere due to human activity averages about 5.1×10^9 ton yr^{-1}.

Observations on atmospheric carbon suggest that only about 40% of this remains airborne, the rest being absorbed by the oceans plus (in Bolin's opinion) a small loss of carbon from the atmosphere created by the regrowth of vegetation following clearance.

There are several points concerning the clearance of forests and their replacement by agricultural systems which must be considered carefully. First, there is the extent of forest cover on our planet; Bolin suggests that dense forest covers about 30% of the Earth's land surface and contains about 90% of the Earth's living biomass. Obviously, clearance of forest results in an initial movement of carbon from a living reservoir to the atmosphere, since most forest clearance is accompanied by the burning of waste timber, and most wood used for construction or pulp will be converted into CO_2 after a lag phase (which will be very short in the case of pulp).

Although the forests represent a major carbon reservoir, it would be wrong to consider them all as an efficient carbon sink. Most natural forest vegetation is at or near a climax or equilibrium state. Biomass is at or close to the maximum attainable within the existing constraints of climate, which means that the gross production of the system will be matched by the combined respiration of autotrophs and heterotrophs (herbivores, carnivores, detrivores and decomposers) within the system (see Odum *Science* **164,** 262; 1969). Thus the climax forest is in a no-growth situation and its carbon uptake will be equalled by its carbon loss. Even fairly mature forests which have not yet attained climax conditions may be past their peak in terms of net ecosystem production.

Thus, to act as an efficient sink for atmospheric carbon, an ecosystem should ideally have a high net ecosystem production rate. The net primary production rate is not necessarily a good index of net ecosystem production. According to Odum net ecosystem production (biomass growth rate) reaches a peak in mid stages of succession.

If one were to consider forest clearance purely from the point of view of global carbon balance (which is, of course, equivalent to wearing ecological blinkers), it represents the creation rather than the destruction of a carbon sink in that it revitalises successional processes. It raises atmospheric carbon, however, by converting biomass carbon to CO_2 and by accelerating the decomposition of soil organic matter and plant litter.

The question must be raised whether one could use a fast-growing terrestrial biomass to compensate for the industrial injection of fossil carbon into the atmosphere. Some of the possibilities in this sphere have recently been considered by Dyson (*Energy* **2,** 287; 1977). Dyson concentrates upon the use of fast growing tree species and also wetland plant species as possible implements for atmospheric CO_2 control. For

---

Peter D. Moore is a lecturer in the Department of Plant Sciences at King's College, London.

example, the American sycamore (*Platanus occidentalis*) has a production capacity equivalent to 750 tons of carbon km^{-2} yr^{-1}. At this rate one would need 7×10^6 km^2 to be planted with the tree in order to compensate fully for rising global atmospheric CO_2. Dyson claims that the United States could provide 7×10^5 km^2 of suitable land, but he fails to take into account the loss in CO_2 consumption resulting from replacement of low grade forest currently occupying such areas. Even more important is what you do with the crop once it reaches maturity. The essence of atmospheric CO_2 control is to lock up the carbon in an alternative, permanent reservoir. Sadly, organic carbon is only too readily oxidised and returned to the atmosphere as CO_2. It could be retained as a forest biomass, but pressure on land is unlikely to permit this.

A natural ecosystem, with an additional built-in carbon reservoir is the peat-forming system. But the bulk of the world's peatlands occur in high latitudes, are generally low in nutrients and have low productivity. International Biological Program data collated in *Primary Production and Production Processes, Tundra Biome* (edited by Bliss & Wielgolaski, Dublin, 1973) show that most tundra mires have annual productivities of only about 40–100 g m^{-2}. The raised mires of Britain have average peat accumulation rates of only about 4–10 cm per century (Hibbert & Switsur *New Phytol.* **77,** 793; 1976). Thus these systems cannot be regarded as very efficient carbon sinks. The more productive wetlands, such as *Typha* and *Phragmites* swamps and ecosystems dominated by the tropical water hyacinth (*Eichhornia crassipes*), present problems of carbon storage and the inhibition of decomposition.

One of the most critical limitations on any such use of biomass growth as a carbon sink is the energy expenditure necessary for the establishment, management, fertilisation, harvest and storage of the crop. Where energy consumption is still closely linked with CO_2 production one wonders whether any attempts at biological control of CO_2 will prove self-defeating. □

New quarks . . . now the good news

from D. Morgan

A conference on Particle Physics was held at Budapest on July 4–9, 1977.

THIS year's high energy physics conference held at Budapest provided a rich harvest of new experimental results powerfully reinforcing present trends in the subject. Most challenging was the report by Leon Lederman (Columbia University) of a new vector meson or group of vector mesons at 9.5 GeV which could very well signify a new form of hadronic matter. Great interest also attached to the first results of neutrino experiments on the new 400 GeV European SPS accelerator at CERN, Geneva. Both these and many other of the results reported at the conference bear on an outstanding theme of contemporary particle research—the structure of matter as seen through the weak and electromagnetic currents.

Present thinking is here dominated by a fusion of two sets of ideas—the unified gauge theories of weak and electromagnetic (current) interactions, and the quark parton model which extends the description of current interactions to the world of strongly interacting particles. The outcome is a very close analogy between the non-strongly interacting 'leptons' (the electron, the muon and their associated neutrinos) and the quarks from which the strongly interacting 'hadrons' are built. Before 1974, three types of quark sufficed to build the known hadrons. One of the great successes of the unified model was to predict the existence of a fourth type of quark, a prediction which was triumphantly vindicated by the discovery of the J/ψ family of 'new' particles. An implication of this whole way of thinking is that the best way of studying new types of hadron is through their weak and electromagnetic interactions. Hence the tremendous contemporary emphasis on neutrino experiments, on the study of e^+e^- annihilation and on the observation in hadron collisions of systems decaying to leptons. Objectives are to discover what are the constituents of matter, both lepton and quark, and how they couple to the weak and electromagnetic interactions: which of the alternative gauge theories is that chosen by nature. In a world with just four sorts of quark and four sorts of lepton, a simple possibility is afforded by the $SU(2)\times U(1)$ model of Steven Weinberg and Abdus Salam which successfully predicted the existence of neutral weak currents and which still gives a good description of neutrino phenomena, according to new data presented to the conference. There are nonetheless good reasons for exploring wider possibilities. In the first place, there exists increasingly secure evidence for a new heavy lepton τ of mass 1.8 GeV, which presumably has a companion neutrino ν_τ. The unified models favour schemes with an equal number of quarks and leptons, suggesting the existence of two more new kinds of presumably rather heavy quarks, nicknamed t='top' and b='bottom', and associated effects in the hadron spectrum. The current couplings of the extra quarks and leptons could simply replicate those of their lighter brothers or could take new forms. The place to seek such effects should be in neutrino experiments and in experiments probing the coupling to lepton pairs. Great interest had therefore attached to reports from a counter experiment at Fermilab of an anomalously large production of high mass hadron systems in high energy antineutrino reactions (the so-called 'high-anomaly'). This suggested not only the coupling of a new kind of quark (the bottom quark has suitable properties) but a new kind of coupling involving the opposite (right-handed) helicity states from those implicated previously. It is against this background that the new experiments are to be judged.

Neutrino experiments

The outcome of the new high-statistics CERN experiment reported by Jack Steinberger is completely to demolish the high-y anomaly in anti-neutrino reactions. Both for neutrinos and antineutrinos the new inclusive cross-sections very much reinforce trends previously perceived in experiments at lower energies and in deep inelastic charged lepton scattering. For proponents of new quarks this is the bad news.

New vector meson

The discovery of the new 9.5 GeV vector meson very much mirrors that of the J/ψ (3.1). Like the 3.1, the new 9.5 GeV effect is seen in the $\mu^+\mu^-$ spectrum from very high energy proton–nucleus collisions. The new data comes from an experiment designed with extreme care to maximise the sensitivity to small signals. This results in an extremely clean unambiguous signal for one or more resonances spanning a range of 1.5 GeV centred at 9.5 GeV, the signal being seen against a background which falls smoothly from 4 to 14 GeV. The resolution is insufficient to reveal narrow

structures so a full analogy with the J/ψ and its associated spectrum is not established. Nonetheless, it seems extremely likely that we are getting a first glimpse of a further 'new' spectroscopy involving one or more new quarks—an exciting prospect for the new e^+e^- storage rings at Cornell, Hamberg, Novosibirsk and Stanford which will be capable of studying the new effects with much better resolution.

Many other new results and problems were discussed at the conference. From Stanford came news of a new recruit to the J/ψ spectrum of mass 3.77 GeV which provides rather striking confirmation of the accepted picture of these states. (It is of course upon this picture that the optimistic hopes for a further new spectroscopy depend.) There was also progress in the field of 'old' mesons with indications that the long awaited A_1 axial vector meson may at last have been established; also reported signals for new vector mesons in the 1–2 GeV range. A further intriguing contribution concerned very narrow effects seen in $\bar{p}p$ annihilation. There continues to be much speculation as to the structure of the weak interactions and of the lepton spectrum. With couplings as in the Weinberg–Salam model, one predicts specific parity violating effects in atomic spectra, effects which have been sought and not found in recent experiments at Oxford and Seattle. The consequent urge to examine alternative coupling schemes was for a time reinforced by unconfirmed reports of an appreciable $\mu \rightarrow e\gamma$ decay rate. It is natural to associate such lepton number non-conserving processes with non-vanishing neutrino masses. The consequent possibility of neutrino mixing was discussed at the conference by Bruno Pontecorvo. A further unresolved question in the field of leptons is posed by the observation of trimuon events of which a small number, mostly involving very large muon momenta have been observed by the same Fermilab group which saw the former high-y anomaly. Despite the current preoccupation with leptonic probes, the quark structure of hadrons is also being explored in wide angle hadron–hadron collisions notably at the CERN ISR from which came further information on the formation of hadronic jets. The outstanding problem for theorists is to understand the detailed mechanism for confining quarks in hadrons. Several interesting lines of work were reviewed but we still await solutions. A high spot of the conference was an evening lecture by Paul Dirac describing his epoch making discoveries of 50 years ago—an object lesson in how to find solutions, and in humility. ☐

Physicochemical hydrodynamics

from Stanley Bruckenstein

> The Levich Birthday Conference was held in Oxford on 11–13 July, 1977.

THE Conference, organised to honour Benjamin G. Levich's 60th birthday, aimed at assessing the present state of development of physicochemical hydrodynamics and its future thrusts. Physicochemical hydrodynamics was the name coined by Levich in 1952 to describe problems related to the influence of fluid flow on chemical or physical transformations, as well as the influence of physicochemical factors on fluid flow. The ideas in Levich's 1952 book and the Soviet work underlying it, were for the most part, overlooked until 1962 when his monograph was translated from the Russian into English. Almost immediately, research in certain aspects of electrochemistry and fluid mechanics began to reflect the influence of the Soviet literature and the Oxford Conference is a measure of western progress and innovation made in the past 15 years in this interdisciplinary field. About 70 papers were presented in two parallel sessions, which were attended by more than 100 chemists, engineers and physicists. The conference concerned itself with six topics: physical transport, interface mechanics, interspersed phases, chemical hydrodynamics, electrochemistry and physics.

The use of controlled mass transport in experimental electrochemistry has made a tremendous impact. The principal convective–diffusion controlled electrode systems in use today are based on the rotating disk and rotating ring-disk geometries. Semitransparent disks are being used to detect electrode intermediates produced photochemically in the diffusion layer adjacent to the electrode surface (W. J. Albery, Oxford University). It has been demonstrated that the quantum efficiency for the photochemical generation process is readily determined from the angular velocity dependence of the current, and the technique is now being applied to investigate the mechanism and efficiency of photogalvanic cells based on dissolved, absorbing species.

Electrochemical photogalvanic cells represent a particularly attractive technology for solar power generation, since in principle they are free of some of the problems associated with solid state solar cells. There is no need to match the physical properties of the materials forming the junction in a solution cell and polycrystalline semiconductor electrodes have already yielded power efficiencies greater than 5%. However, liquid solar cells have their own unique problems, one of which is photocorrosion of the semiconductor. Rotating ring-disk and sinusoidally modulated rotating disk electrodes were used (B. Miller, Bell Laboratories, Murray Hill, New Jersey) to study polycrystalline cadmium sulphide semiconducting electrodes in $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ and S^{2-}/S_x^{2-} media. Details were given on the means for establishing the potential at which significant photocorrosion begins. The S^{-2}/S_x^{2-} system was found to be far less susceptible to photocorrosion.

The use of electrochemistry as a tool to study fluid dynamics is becoming more common. Non-newtonian fluid studies at rotating disk electrodes have led to the verification of an inversion of flow direction at a critical rotation speed. Also drag reduction in turbulent flow in the presence of poly(ethylene oxide) has proved especially amenable to study with the rotating disk and rotating ring electrodes (L. Viet, CNRS, Paris).

A rotating disk study of the chemical vaporisation of silicon (M. L. Hitchman, RCA, Zurich) from $SiCl_4$ and H_2 permitted the separation of transport and chemical processes, and the determination of the heat of activation for the silicon deposition process. This approach appears to hold considerable promise for the study of analogous gas–solid reactions.

G. K. Batchelor presented Levich's plenary paper. Levich, who requested permission to emigrate from the Soviet Union several years ago, was not allowed to attend the conference. This paper was a comprehensive review of the entire field and delineated problem areas. In the discussion of heterogeneous chemical kinetics, the necessity for uniform accessibility of a surface, or calculable mass transport rates, was stressed. The paradox of the existence of a rigorous statistical theory and several semi-empirical theories of

---

S. Bruckenstein is Professor of Chemistry at the State University of New York at Buffalo.

turbulence was discussed. Levich remarked that, despite their obvious weaknesses, the semi-empirical approaches did permit successful calculations in very complex flow situations. There is need for a more detailed study of the structure of turbulence at rough walls. Levich believes that the phenomena of higher viscosity at the interface of two fluids is due to the presence of surface active agents, not a "surface viscosity". The mechanism of the breaking of bubbles in liquid media, ascribed to internal motions of the gas in the bubble is not yet confirmed by convincing experimental data. In his discussion of statistical systems (a stochastic and disorderly flow regime in space and time) a number of unsolved problems were discussed, including that of rising bubbles in a liquid, breaking of a gas stream through a liquid layer, and the process of heat and mass transfer in a system of bubbles. ☐

Isotherm limits ocean magnetism

from Peter J. Smith

THE linear marine magnetic anomalies which have provided such important evidence for seafloor spreading must result from magnetised material within the crust and, possibly, the uppermost mantle. To say that, however, is to state little more than the obvious, although to go beyond it is difficult. With insufficient direct information from, say, deep drilling into the ocean floor it is impossible to constrain the variables in theoretical models of the magnetised zone in such a way as to provide a unique solution, even when the model is made unrealistically simple. For example, the deceptive regularity of the anomalies themselves gave rise in the first instance to an overly simplified model comprising alternating blocks of normally and reversely magnetised rock; but the magnetisations and vertical thicknesses of the blocks could be varied independently within certain limits to permit a large number of viable block arrangements.

In early versions of the alternating block model, block thicknesses ranged up to at least 9 km. Later, however, Carmichael (*Can. J. Earth Sci.* **7**, 239; 1970) and others concluded that if the high magnetisations found in rock samples dredged from the ocean floor were typical of those throughout the blocks, the magnetic layer could be as thin as 0.4–1.0 km. Indeed, this view proved so popular that the most common block thickness used in anomaly modelling ever since has apparently been 0.5 km (with magnetisations in the range 8×10^{-3}–20×10^{-3} emu cm^{-3}). But as Kristjansson and Watkins (*Earth planet. Sci. Lett.* **34**, 365; 1977) now re-emphasise, no one should make the mistake of regarding this thickness as anything more than a "computational artifact". It serves a useful purpose in anomaly modelling but bears little relation to reality.

The reality is that the zone producing the observed anomalies is likely to be structurally complicated, chemically and mineralogically inhomogeneous, the product of emplacement within an active ridge zone of variable width, and affected by post-emplacement rotation. Such complexities are currently the subject of intense study, and models which attempt to accommodate them are already beginning to appear. Kristjansson and Watkins, on the other hand, have taken a more direct approach in seeking information about the actual thickness of the magnetic zone beneath the active central volcanic area of Iceland. This area is, of course, the landward continuation of the oceanic Reykjanes ridge; and although the magnetic anomalies are less sharp than those over oceanic ridges proper, they may still be used to determine a magnetic zone thickness. Thus if the zone has an average magnetisation comparable to that of the surface basalts (15×10^{-3}–20×10^{-3} emu cm^{-3}) it need only have a thickness of 0.5 km to permit modelling of the overlying anomalies. Alternatively, if the observed proportion of tuff and breccia at the surface is taken to obtain at depth, the net magnetisation is more likely to be 6×10^{-3}–8×10^{-3} emu cm^{-3}, leading to a magnetic zone thickness of about 2 km. Either way, the "computational" thickness is not very great.

But again the reality is different, at least if the magnetic properties of igneous samples from eight deep (up to 2 km) boreholes are anything to go by. The room temperature magnetic susceptibility, for example, is highly variable (depending to some extent on rock type) but shows no systematic change with depth up to the 2 km limit. And since the boreholes lie in regions of high thermal gradient, geothermal activity and recent volcanism, this is equivalent to saying that the susceptibility shows no systematic change within zones having present temperatures of up to about 300 °C. Outside the highly thermal areas, however, the 300 °C isotherm corresponds to a depth of about 4.5 km. The implication therefore is that beneath parts of the central volcanic area of Iceland the magnetic zone extends to depths of at least 4.5 km.

This is much greater than the greatest depth deduced from magnetic anomalies, confirming that the latter is indeed a fiction. It also suggests to Kristjansson and Watkins that to think in terms of a physically discrete magnetic layer of any thickness is fundamentally wrong—a point which needs to be made if only because some workers have already shown a tendency to translate a mathematical convenience into a sort of reality by thinking aloud in terms of a distinct magnetic layer with a base accessible in principle to sampling (for example, by the Deep Sea Drilling Project). The point that Kristjansson and Watkins wish to emphasise is that in their view there is absolutely no reason to suppose that the lower limit of magnetisation, which must exist, is governed by anything other than the Curie point isotherm. Or to put it another way: there is no reason to suppose that the material immediately below the magnetised zone is any different from that in the zone itself. The former is simply at a temperature high enough to preclude its being magnetised. ☐

Magnesium and energy

from E. F. Emley

An international conference on Energy Conservation in Production and Utilisation of Magnesium was held at the Massachusetts Institute of Technology on 25–27 May, 1977. The conference was co-sponsored by the MIT Center for Materials Science and Engineering, the US Energy Research and Development Administration (ERDA) and the International Magnesium Association.

"IN the opinion of knowledgeable materials engineers, magnesium is a structural metal whose time has come". This opening sentence from the announcement set the tone of the conference, which set out under the guidance of M. C. Flemings to "create a meaningful dialogue among industrial, university and government personnel that will lead to energy con-

---

E. F. Emley is Group Chief Metallurgist of the British Aluminium Company Ltd.

servation in the production of magnesium and through its utilisation".

For many years the use of magnesium has been hindered by factors such as limited sources of supply of the metal and smallness of demand—about one fiftieth of that for aluminium—which in turn have prevented realisation in production of the benefits of scale. General structural and aerospace uses have tended to decline and the growth of demand has reflected increasing use for non-structural applications, such as alloying with aluminium and desulphurising steel. Realisation that magnesium is a non-strategic material (sources, including seawater, are inexhaustible and very widely distributed) coupled with the possibilities of energy saving in applications where weight or inertial forces are important, has brought nearer the time when new investment on a scale that could lead to cost reductions can be contemplated. Meanwhile, important improvements to both the electrolytic and the thermal reduction routes were announced at the conference, and these alone should lead to substantial reductions in energy consumption and production cost.

At the first session, J. A. Barclay (US Bureau of Mines) set the scene by calculating the relative total energy consumption for producing aluminium and magnesium, and suggesting directions in which improvements might be sought. Converted to kwh(t)/tonne, his figures were 71,500 for aluminium by the Hall-Héroult route and 105,000 for magnesium by the Dow seawater electrolytic process, with savings of 9% and 6% for the ferrosilicon (Pidgeon version) and carbothermic processes respectively. Comparative figures presented by P. Lugagne (Société Française d'Electrometallurgie) indicated a net energy consumption of 76,500 kwh (t)/tonne for the Magnetherm version of the silicothermic process, which includes allowances for the energy content of saleable by-products amounting to about 15% of the total. A similar energy credit would be available to the electrolytic process if starting from brine, by selling the by-product chlorine. Looking to the future he foresaw that in 1990 the energy requirements to produce 1 tonne of each metal would be virtually the same. In similar vein, projections by R. B. Stein (Bechtel Corporation) indicated that the price curves for virgin aluminium and magnesium could cross about 1985.

It was confirmed at the meeting that Norsk-Hydro will bring on stream next year new plant involving the dehydration of waste $MgCl_2$ brines from the German potash industry. This will give rise to 2.8 tonne chlorine per tonne of metal produced, and lead to a substantial net energy gain. Dow have an apparently similar development in hand which is expected to result in an energy saving of 30%.

A high spot at the meeting was the announcement that J. M. Avery, well known for his contributions to blast-furnace technology, had invented a continuous version of the Magnetherm ferrosilicon reduction process, operating at atmospheric pressure, and that agreement had been reached with the Arthur D. Little organisation to evaluate the process.

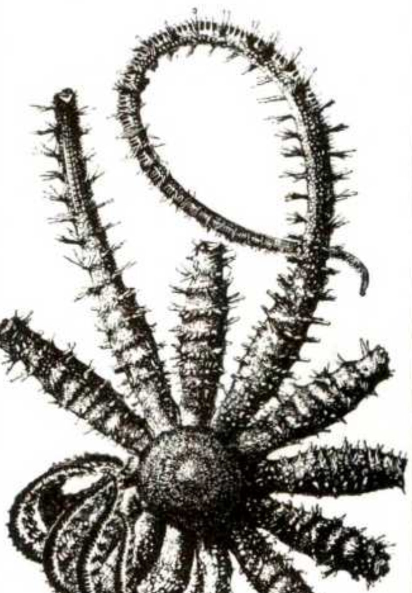
Following consideration of primary production, the conference turned to energy usage in fabrication, and the comprehensive data of S. L. Couling (Battelle), showed that the most favourable fabricating method, in terms of energy requirement, is hot-chamber die-casting. To deform equal volumes of aluminium or magnesium requires roughly the same energy, but less efficient furnaces and higher melt losses increase the energy requirements for wrought magnesium, as does the practice of pre-extruding stock for the extrusion process.

As regards growth of structural uses, M. S. Holland (Ford Motor Co.) saw the potential for magnesium in the automotive field as excellent, but not at the present price. With a primary Mg/Al price ratio of 2 : 1, as at present, the 1985 potential is seen as 5,000–10,000 t, whereas with a price ratio of 1.5 : 1 it could be as high as 100,000 t—more than the present day total US usage. Overall energy changes on replacing steel by aluminium or magnesium were further considered by J. P. Clarke and G. S. Kennedy (MIT) who found total energy requirement ratios close to 1.45 : 1 for each of the light metals compared with steel as unity when non-transport applications were considered. In automotive applications there can be an energy credit for the light metals owing to weight reduction and consequent fuel savings during the operational lifetime of the component, and this advantage is about 80% greater for magnesium than for aluminium.

The last day of the conference was devoted to R and D Workshops dealing with fabrication, properties, recycling, policy and, by popular request, primary extraction. Several workshops stressed the importance of price, and the need to get down to a price ratio of 1.5 compared with aluminium. Meanwhile the use of hot-chamber die-castings should be promoted, but there is need also for lower cost sheet and extrusions, for a metal-cleaning method without using flux, for a way of recovering metal from crucible residues, for ways of removing nickel, copper and tin from scrap, for reducing magnesium losses in the aluminium industry, for new approaches to sheet such as strip-casting and the pendulum mill, for avoiding the scalping and double extrusion of billet, for better or cheaper systems of protection against corrosion, for die-casting alloys with better elevated-temperature properties and reduced tendency to surface segregation, for stronger wrought alloys—the needs are many and the challenge to the technologist, whether in industrial, academic or government service, is great. □

NATURE

A hundred years ago



NEARLY a quarter of a century ago the celebrated poet and naturalist P. Chr. Asbjornsen, was dredging in the interior of the picturesque Hardanger-fjord, when, at a depth of about 200 fathoms, the dredge brought up a wonderful new star-like Echinoderm, quite unlike any form that had been up to that moment described.

In its unlikeness to most recent forms of star-fishes he saw its connection with certain fossil forms, and in its brilliant sun-like form he was reminded of the "Brising" which, according to ancient Norwegian tradition, was concealed by Loke in the abyss of the primeval ocean, but which had so long served as the ornament to cover the breast of the god Freya, and he gave the name of Brisinga to the new genus.

The lifetimes of both positive and negative relativistic ($\gamma = 29.33$) muons have been measured in the CERN Muon Storage Ring with the results

$$\tau^+ = 64.419\ (58)\ \mu\text{s}, \quad \tau^- = 64.368\ (29)\ \mu\text{s}$$

The value for positive muons is in accordance with special relativity and the measured lifetime at rest: the Einstein time dilation factor agrees with experiment with a fractional error of 2×10^{-3} at 95% confidence. Assuming special relativity, the mean proper lifetime for μ^- is found to be

$$\tau_0^- = 2.1948\,(10)\ \mu\text{s}$$

the most accurate value reported to date. The agreement of this value with previously measured values of τ_0^+ confirms CPT invariance for the weak interaction in muon decay.

MEASUREMENT of the lifetime of a sample of radioactive material which is moving with a known velocity is a means of testing the so-called time dilation, or slowing down of moving clocks, predicted by the special theory of relativity. If, in addition the radioactive particles move in closed circular orbits then the conditions simulate those of the outward and return journey of the twin paradox in which, according to the theory, the journeying twin ages more slowly than the one who stays at home. In this situation it is also possible to search for any modification of the predictions of the theory due to acceleration.

A device which stores unstable elementary particles of high momentum is an excellent tool with which to carry out such measurements and here we report the results obtained with the Muon Storage Ring at CERN. Muons have a lifetime at rest of about 2.2 μs and decay into electrons neutrinos and antineutrinos

$$\mu^- \rightarrow e^- + \nu_\mu + \bar{\nu}_e$$

The decay electrons are readily detected. If the muon sample has a velocity v then the lifetime of the sample as measured in the laboratory is given by

$$\tau = \tau_0/[(1-(v/c)^2)^{\frac{1}{2}}] = \gamma\tau_0$$

where τ_0 is the lifetime for the particle at rest.

The previous Muon Storage Ring experiment at CERN reported[1] a value of the muon lifetime in flight for a relativistic factor $\gamma \simeq 12$, which agreed within 1% with the predicted value obtained by applying the above Einstein time dilation factor[2] to the measured lifetime at rest[3]. Here we report separate measurements for μ^+ and μ^-, with a γ factor of 29.33, which are an order of magnitude more precise and which show that the predictions of special relativity obtain even under accelerations as large as 10^{18} g and down to distances less than 10^{-15} cm.

In the latest Muon Storage Ring[4–9] muons of momentum 3.094 GeV/c ($\gamma \simeq 29.3$; $\beta = v/c = 0.9994$) circulate on orbits of 14 m diameter in a uniform magnetic field and a weak focusing electric quadrupole field[10]. The main purpose of the project was to measure the anomalous magnetic moment of the muon by observing the relative precession of its spin with respect to its momentum. The muons are born from pion decay

$$\pi^- \rightarrow \mu^- + \bar{\nu}_\mu$$

and by careful momentum selection in this process it is possible to obtain a circulating muon sample with high initial longitudinal polarisation. Decay electrons from the stored muons are detected in 20 shower counters inside the ring. By selecting only high energy electrons (forward going in the muon rest frame) it is possible to follow the muon spin precession since the decay electron distribution is assymetric with respect to the muon spin direction. The decay times are measured to high precision[11–13] so that the muon laboratory lifetime can be obtained by fitting the observed decay electron time spectrum which consists of an exponential decay modulated by the muon spin precession frequency (ω_a).

This spectrum is distorted by small systematic effects, however—notably the loss of muons from the trapping region before decay, the dependence of the background count rate, and the variation of the decay electron detection efficiency as a result of gain changes during the muon storage period. The resulting modification to the normal modulated exponential decay spectrum may be expressed as

$$N(t) = N_0[1+SG(t)+F(t)]\{\exp(-t/\tau) \times \times [1-A\cos(\omega_a t+\varphi)]+B(t)\} \quad (1)$$

The functions $SG(t)$ and $F(t)$ represent the variation of detection efficiency and muon losses, respectively, while $B(t)$ is the background. For μ^- data the background is independent of time and at the negligible level of $\sim 2\times 10^{-5}$, but becomes more important in the μ^+ lifetime data owing to stored proton contamination. The minimisation and measurement of these systematic effects are discussed in some detail below.

Muon losses

The muons are injected by the decay in flight of 3 GeV/*c* pions inflected into the ring[4-9]. They initially fill the whole available phase space; however, particle loss involves preferentially those muon orbits which approach closest to the material limits of the storage region.

To reduce these losses we manipulate the muon orbits in the first few microseconds after injection (the rotation period of the muons is 0.147 μs) so that the muons which pass within ~1 cm of the walls are removed. The remaining muons are left in the central region of the aperture and have a much smaller probability of being lost. This 'scraping' is achieved by applying asymmetric voltages to the electrostatic quadrupoles[10] used to focus the particles. A vertical electric field shifts the median plane downwards, and simultaneously a horizontal electric field (outwards on one side of the ring, inwards on the other) shifts the orbit sideways. The muons of large betatron amplitude then strike appropriately located aperture stops. The scraping voltages are turned off with a time constant of 10 μs, allowing the muon population to return adiabatically to the centre of the storage region.

When a muon hits an obstacle it loses energy and has a high probability of emerging on the inside of the ring. The muon losses are therefore monitored by placing a detector against the vacuum chamber on the inside of the ring, in a position similar to that occupied by the decay electron detectors. The muon detector consists of a series of four scintillation counters each preceded by two-radiation-length lead converters. Muons are discriminated from electrons on the basis of pulse height. A 'muon' is defined as a particle which, for all four counters, gives a pulse height equivalent to that of a minimum ionising particle, the acceptance ranging from 50% below to 50% above this central value. Measurements in an electron beam show that for the relevant range of decay electron energies, this condition rejects electrons by a factor of ~700. The muon detector is used to optimise the *n* value of the focusing field for minimum muon losses, to test the scraping system, and to measure the loss correction $F(t)$.

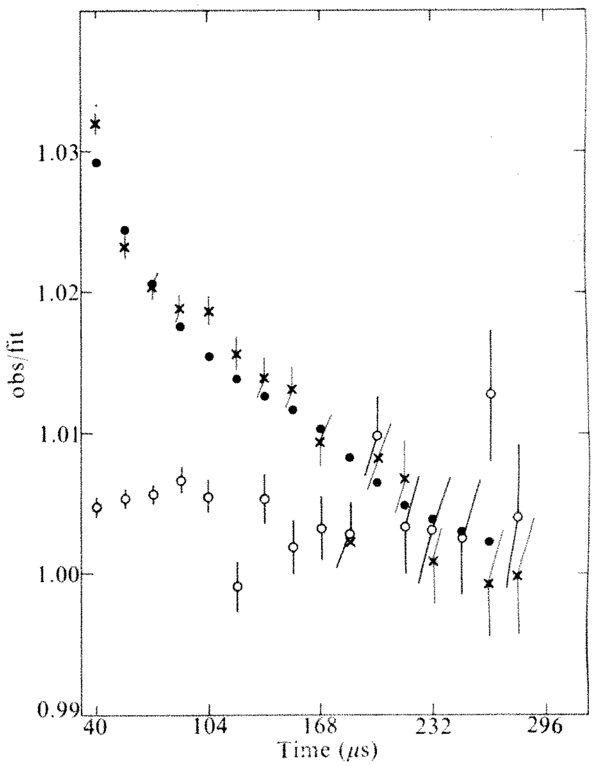

Fig. 1 Ratio of the decay electron time distribution (obs) to an exponential fit (fit) in the time range 300–650 μs. The *g*-2 modulation is included in the fit. The excess counts at early times over the extrapolated fit function show the effect of muon losses. ×, obs/fit no scraping. ●, Muon loss function as calculated from the muon detector time spectrum. ○, obs/fit with scraping.

In the optimum running conditions very few muons were lost after 100 μs. The above rejection ratio and the similarity in acceptance of the muon and electron detectors indicated that $\gtrsim 80\%$ of the 'muon' counts after this time were mis-identified electrons. This was confirmed with a small five-gap optical spark chamber placed behind the muon detector. Muons, identified by a straight track with four or five sparks, were found to form only 10% of the late time 'muon' counts.

The correction function $F(t)$ in equation (1) is given in terms of the lost muon time spectrum $M(t)$ (corrected for decay electron background) by the integral

$$F(t) = \frac{1}{\varepsilon\tau N_0}\int_t^{t_L} M(t)\exp(t/\tau)\,\mathrm{d}t \quad (2)$$

where t_L is the end of the storage period and where the factor ε is the ratio of the detection efficiencies of the muon and electron detectors; its value and hence the absolute calibration of the muon detector is obtained as follows. In data where the losses are relatively high (those taken without scraping in operation), $F(t)$ can be deduced directly from the decay electron time distribution. Comparison with the values obtained from equation (2) provides the calibration of the muon detector and checks that it samples the lost muons in an unbiased way at different times.

This procedure and the effectiveness of the electric scraping are illustrated in Fig. 1. The points (*a*) represent the fractional

Table 1 Results for the muon lifetime in flight (μs)

Run	A	B	C	D	E	F

Fully corrected lifetime (total error)	64.442 (69)	64.363 (108)	64.447 (59)	64.346 (42)	64.408 (87)	64.306 (64)

Table 2 Lifetime results (μs)

	μ^+	μ^-	Weighted average $\mu^+ + \mu^-$
Lifetime in flight (this experiment)	64.419 (58)	64.368 (29)	64.378 (26)
Lifetime at rest (this experiment)	2.1966 (20)	2.1948 (10)	2.1952 (9)
Lifetime at rest (previous best measurements, refs. 18, 19)	2.19711 (8)	2.198 (2)	—

excess decay electron counts at early time with respect to a fit to the unscraped data at late time ($t > 300$ μs). Taking 40 μs after injection as $t = 0$, gives $F(0) = 0.03$ for these data. The points (*b*) are those calculated from the lost muon data, and the time dependence of these two data sets are in excellent agreement. The points (*c*) are the early time excess counts for the scraped data obtained in just the same way as (*a*). The calibrated muon detector gave a value $F(0) = 0.001$ in this case, so the loss level at 40 μs after injection is improved by a factor of ~30.

For the late starting times chosen in the analysis, the muon losses contribute at most a shift of 0.02% in the lifetime, as can be seen from the entries in Table 1.

Proton background

For the μ^+ data there is another complication in that the time-varying electric field associated with scraping enables protons to be stored in the ring. (The incident π beam is unseparated.) These protons are lost with a characteristic time distribution and so give background in both the decay electron and muon detectors. By assuming that the muon losses are the same for $\mu^\pm$ with identical machine parameters, the time distribution of these lost protons can (by subtraction) be found from the counts recorded in the muon detector. The relative detection efficiency of the muon and electron detectors for these protons is established in a separate experiment where the electric field is switched off ~1 ms after injection. At this time (~15.5 τ) only protons are stored, and the ratio of counts seen in the muon and the electron detectors directly gives the efficiency ratio. It turns out that the background level in the decay electron counts due to these 'unstable' protons is low ($\sim 3 \times 10^{-3}$ at 32 μs after injection) so the resulting correction to the lifetime is small, as shown in Table 1. The contamination of the μ^- data by stored antiprotons was at a negligible level.

Gain effects

The largest systematic effect which must be considered is the change in the energy acceptance of the decay electron detection system as a function of muon storage time. This effect is due to gain changes following the injection into the ring of one or more ~10 ns wide bunches containing $\sim 10^7$ particles (for more details of the effect of high particle flux on the gain of photomultipliers, see ref. 14); it is minimised by blanking off the dynode chain of the photomultiplier during, and for a few microseconds after, injection

The system gain is measured as a function of time by means of light-emitting diodes (LEDs). The injected beam and all other conditions are the same as in normal data-taking. The signals from the LEDs are distinguished from decay electron counts by timing; a series of pulses are input to LEDs on the photomultipliers of the electron detectors at a number of fixed times throughout the muon storage interval. The output signal from each electron detector is split and input to two discriminators with a threshold separation of 3 dB. The LED pulse heights are adjusted so that all pulses fire the lower threshold discriminator and ~50% of the pulses fire the higher one, that is, the threshold of the latter is at the maximum of the LED pulse-height spectrum where the sensitivity to gain changes is greatest. A subsidiary calibration measurement of the pulse-height distribution for each LED-photomultiplier combination is made to establish the quantitative relation between the ratio of the counting rates output from the two discriminators and the gain change ΔG.

The gain curve is measured typically at 11 points between 7 and 580 μs for each counter, with a precision per point of ~0.1%. From the gain curves thus obtained, a counter selection is made to remove from the analysis counters with a steep gain variation. These counters are the ones which are struck preferentially by the injected beam. The mean gain curve of the remaining counters is typically flat to within ~0.1% over the whole muon storage interval. The mean gain curve $G(t)$ is multiplied by the factor $S = \Delta N/(N\Delta G)$, the fractional change of counting rate of the decay electrons per unit gain change, to give the correction function in equation (1). For the electron energy threshold chosen for the lifetime analysis, $S = 1.00 \pm 0.02$.

The error in the gain correction was estimated by repeated measurement under identical running conditions. From the consistency of the slopes of mean gain curves measured at intervals of both a few days and several hours apart, this error is conservatively estimated to be ~0.03% in τ.

Results

Values of the muon lifetime in flight τ were found by fitting the experimental decay electron time distribution to the six-parameter function of equation (1) using the maximum likelihood method and varying the six parameters N_0, τ, A, ω_a, φ, B_0, where B_0 is the time-independent part of $B(t)$.

The results obtained for the lifetime for the two μ^+ and four μ^- runs which were separately analysed are presented in Table 1. The uncorrected lifetime, and the corrections with estimated systematic errors due to muon loss and gain effects, are shown for each run. In addition, for the μ^+ data, the proton background correction and error are shown. The starting times quoted for the fits vary from run to run as, according to the beam intensity used, the muon detector took varying times to regain full efficiency after injection. In all cases the upper limit of the time range of the fit is 650 μs.

The weighted average values of the lifetimes in flight for $\mu^\pm$ together with the combined average are given in the first line of Table 2.

Fig. 2 Bunch structure in the Muon Storage Ring from 6–10 μs after injection. Each bunch corresponds to one turn in the ring. Such distributions are analysed to give the mean rotation frequency f_{rot} of the stored muons, and hence the mean γ-factor $\bar{\gamma}$.

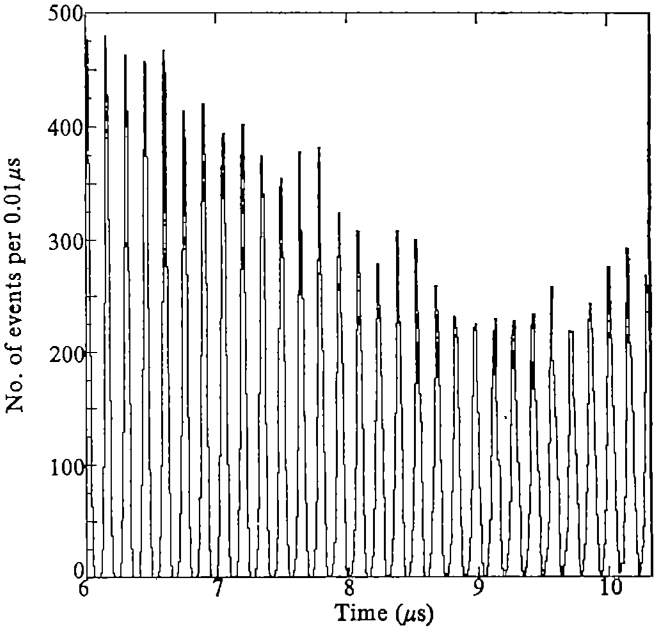

Table 3 Tests of relativistic time dilation from particle lifetime measurements. Values of $\tau_0 = \tau/\gamma$ are compared at different γ values

Particle	Refs	γ_1	γ_2	$[\tau_0(\gamma_1) - \tau_0(\gamma_2)]/\tau_0(\gamma_1)$ (%)	95% confidence limits (%)
$\pi\pm$	19–22	1.0	2.44	-2.5 ± 0.9	-4.3 to -0.7
$K\pm$	23, 24	1.0	3.38, 4.17	0.9 ± 0.3	0.3 to 1.5
K_S°	25, 27	1.63	15.2	0.5 ± 0.6	-0.7 to 1.7
K_S°	25, 26	1.63	20.2	0.2 ± 0.7	-1.2 to 1.6
μ^+	18 and this work	1.0	29.3	0.02 ± 0.09	-0.16 to 0.20

In the second line of Table 2 are given the corresponding lifetimes at rest τ_0 calculated using the Einstein[2] relation

$$\tau_0 = \tau/\gamma, \quad \gamma = [1-(v/c)^2]^{-\frac{1}{2}}$$

The average value of γ for the circulating muons is found by analysis[1] of the bunch structure of the stored muons (see Fig. 2) over a period of $\sim 40\ \mu s$ after injection. The mean rotation frequency $\bar{f}_{rot}$ is related to the average γ value $\bar{\gamma}$ by the expression

$$\bar{\gamma} = 2\lambda \bar{f}_p / g \bar{f}_{rot}$$

where $\bar{f}_p$ is the proton magnetic resonance frequency[15] (corrected to vacuum[16]) corresponding to the mean magnetic field, g is the g-factor of the muon, and $\lambda = \mu_\mu/\mu_p$ is the ratio of the muon and proton magnetic moments[17]. The result for $\bar{\gamma}$ is found to be

$$\bar{\gamma} = 29.327\,(4)$$

where the quoted error corresponds to an uncertainty of ± 1 mm in the mean radius of the distribution of circulating muons.

The last line in Table 2 gives the most accurate published values for the μ^+ (ref. 18) and μ^- (ref. 3) lifetimes measured at rest. Comparing the high precision value of the μ^+ lifetime at rest, $\tau_0{}^+$, with the value found in this experiment we obtain

$$(\tau_0{}^+ - \tau^+/\bar{\gamma})/\tau_0{}^+ = (2 \pm 9) \times 10^{-4}$$

At 95% confidence the fractional difference between $\tau_0{}^+$ and $\tau^+/\bar{\gamma}$ is in the range $(-1.6\text{–}2.0) \times 10^{-3}$. To date, this is the most accurate test of relativistic time dilation using elementary particles.

This result is compared in Table 3 with other limits on the validity of special relativity calculated from lifetime measurements given in the existing literature for $\pi^\pm$ (refs 19–22), $K^\pm$ (refs 23, 24) and K_S^0 (refs 25–27).

The entries in the table are the values of, and 95% confidence limits for $[\tau_0(\gamma_1) - \tau_0(\gamma_2)]/\tau_0(\gamma_1)$, where $\tau_0(\gamma_{1,2})$ are the lifetimes at rest as calculated via the Einstein relation using measurements on particles with mean γ values $\gamma_{1,2}$. The present experiment improves on the previously existing upper limits on violations of special relativity by about an order of magnitude.

The μ^+ measurement differs in one important respect from the other results quoted in Table 3. The $\pi^\pm$, $K^\pm$ and K_S^0 measurements in flight were performed in beams for which the decaying particle, regarded as a clock, was in an inertial (unaccelerated) frame. In the muon experiment, however, the particles are subjected to a constant transverse acceleration of 10^{21} cm s^{-2}. The muons perform a round trip and so when compared with a muon decaying at rest in the laboratory, simulate closely the so-called twin paradox which was already discussed in Einstein's first paper[2]. Other experiments[28,29] have confirmed the correctness of relativistic time dilation for clocks in circular motion to $\sim 10\%$ at low velocities (A similar conclusion follows from observations of the second-order (transverse) Doppler effect in the temperature dependence of the Mössbauer effect[23] and of the hydrogen maser frequency[24]). The present experiment is unique in its use of an ultra-relativistic clock ($\gamma \gg 1$) and its much greater precision $\sim 0.1\%$.

The possibility also exists that very large accelerations may modify in some way the internal enstitution of particles[32–35]. No such effects, in so far as they affect the particle lifetime, are seen in this experiment where the transverse acceleration is $\sim 10^{18}$ g.

Some authors[36,37] have suggested that just as special relativity breaks down at very large distances owing to gravitational effects, there may also be a breakdown below some fundamental distance α. Rédei[38] has calculated the effect of such a breakdown on the muon lifetime in flight, and finds a γ^2 correction to the Einstein formula

$$\tau = \gamma\tau_0\,(1 + 2.5 \times 10^{24}\,\gamma^2\alpha^2)$$

where α is in centimetres. From our value of τ^+ a limit can be set on α

$$\alpha \leqslant 9.6 \times 10^{-16}\ \text{cm} \quad (95\%\ \text{confidence level})$$

Assuming the correctness of special relativity, the μ^- lifetime at rest $\tau_0{}^-$ given in Table 2 is the most precise value so far reported. Comparing this value with the high-precision measurement of $\tau_0{}^+$ it is found that

$$(\tau_0{}^- - \tau_0{}^+)/\tau_0{}^+ = -0.00105(46)$$

Or, at 95% confidence level, the fractional difference of $\tau_0{}^-$ and $\tau_0{}^+$ is in the range -0.002 to -0.00013.

The limit set on this quantity, which should vanish[39] by CPT invariance of the weak interaction, is comparable with that set by the best direct measurement[3] of the ratio $\tau_0{}^-/\tau_0{}^+$.

We thank all those who have contributed to this measurement of the muon lifetime. In particular, we thank F. Wickens for early calculations on the electric field configuration; E. M. McMillan for studies of various mechanisms of muon losses; R. W. Williams for analysis of the muon losses from the decay electron data; J. Lindsay for the preparation of a blanking scheme for photomultipliers and S. Wojcicki for his early contributions to the gain measurements.

Deep-sea drilling in the Bay of Biscay and the Rockall Plateau show that passive continental margins are characterised by the absence of seismicity and include continental shelf, continental slope and continental rise physiographic provinces, exemplified by the borders of the Atlantic Ocean.

HYPOTHESES postulated for the structural and stratigraphical evolution of passive margins are based on the available geological and geophysical data, and analogies drawn with present day margins thought to represent stages in margin evolution[1-5]. In the initial stages, rifting of the continent perhaps contemporaneous with regional uplift takes place[6]. When the continental crust is completely rifted apart, ocean crust begins to accrete at the axis of the diverging plates. Heat dissipation[7] through the cooling continental and oceanic lithosphere is thought to result in subsidence, permitting transgression. The subsequent development of the margin depends on the variable roles in both time and space of subsidence, sediment loading, climate and ocean circulation. For example, the lithology and volume of sediments may be influenced by global transgressions and regressions[8,9], although their effects, in turn, depend on the altitudes of the continents and their rate of subsidence.

The relationship between the subsidence history, the rifting environment and the unconformities observed beneath many passive margins is, in particular, poorly understood because of a paucity of relevant deep sea drilling data. We report here some preliminary relevant results from the holes drilled on the passive margins of the Bay of Biscay and the Rockall Plateau during Leg 48 of the International Phase of Ocean Drilling (IPOD) of the Deep Sea Drilling Project (Figs 1, 2, 3).

The Bay of Biscay and Rockall Plateau

The northern margin of the Bay of Biscay[10-14] is comprised of the wide Celtic shelf and a broad continental slope that is dissected by many canyons and broken by the Meriadzek Terrace. Detailed multi-channel seismic surveys made by the Institute Francais du Petrole, the Institute of Oceanographic Sciences and the Centre National d'Exploitation des Oceans, show thin Tertiary and Cretaceous sediments overlying tilted blocks and half grabens that trend sub-parallel to the margin and control the relief of the Meriadzek Terrace (Fig. 2). Previous geological and geophysical studies have suggested that the Bay of Biscay was formed by rifting in Late Jurassic–Early Cretaceous time and by spreading during Early to Upper Cretaceous time[10-18]. However, the relation between the spreading and the subsidence history of the margin is not known. The three sites drilled in Biscay (Fig. 2) form a transect from the upper slope (site 402A) to the lower slope (site 400A) within 40 km of the continent–ocean boundary at the Trevelyan escarpment[18].

In contrast to the Bay of Biscay, three phases of rifting and spreading isolated the Rockall Plateau microcontinent and formed its margins[19-23]. The first opened the Rockall Trough in Early–Late Cretaceous time, and the second, in Late Cretaceous time (76 Myr), opened the Labrador Sea, thus spreading the Greenland–Rockall plate away from North America. In the final phase, rifting and volcanism at about 60 Myr were followed by spreading beginning at 52–53 Myr between Greenland and Rockall. Sites 403 and 404 were drilled in a broad fault-bounded basin some 30 km east of the oldest magnetic anomaly[24] (52–53 Myr), recorded in the adjacent ocean crust. Within the basin, a thick, faulted sequence of deltaic aspect is unconformably overlain by a thin unfaulted sequence (Fig. 2). Sites 405 and 406 were drilled on ocean crust south of the east–west trending transform fault controlling the south-west margin of the Rockall Plateau, and will not be discussed here. The generalised lithology and stratigraphy of the holes drilled during Leg 48 are shown in Fig. 3.

Palaeobathymetry

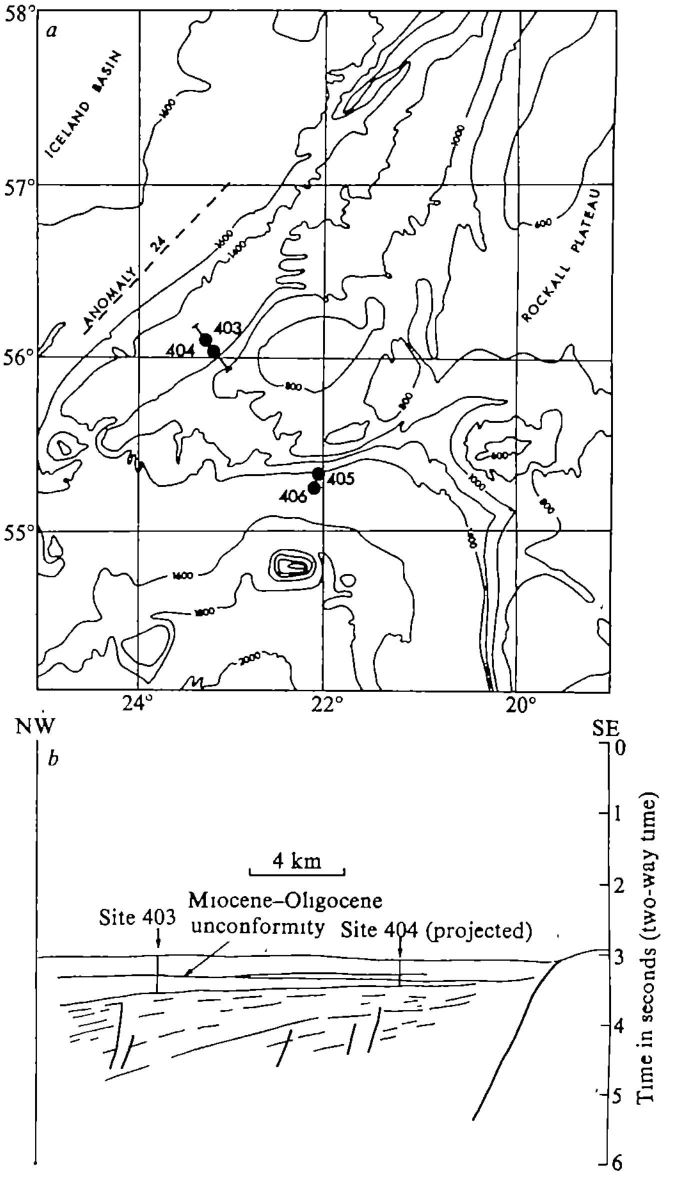
The palaeobathymetric history of the sites has been inferred principally from the macro- and microfossil assemblages, the associated lithologies, and seismic profiles which show the absence of post-rift faulting.

At site 402A (Fig. 1, Fig. 3), now situated on the upper slope of Biscay in 2,317 m depth, the Aptian carbonaceous limestones contain rare radiolaria and benthic foraminifera such as *Nodosaria* sp., *Lenticulina* sp. and *Epistomina spinulifera* indicative of a shallow shelf sea. The microfacies of the Albian limestones, as observed in thin section, are closely similar to the epicontinental Albian of the Aquitaine Basin (P. A. Du Peuble, unpublished data). In contrast, the Middle and Late Eocene nannofossil chalks contain deep-water species such as *Stilostomella* sp. However, shallow-water species, that may be displaced, are common and include *Bolivina* and *Rosalina*. The deep-water fauna suggests a depth of 1,000 to 1,500 m. The Pliocene and Pleistocene foram nanno oozes were apparently deposited at the present depth.

At site 401 (Fig 1, Fig. 3), located on the edge of the Meriadzek Terrace in 2,555 m depth, the oldest sediments encountered were Jurassic (Kimmeridgian–Portlandian) limestones containing echinoderm and pelecypod debris, algal and coral fragments, indicative of a shallow-water reefal environment. Tithonian calpionellid limestones have been dredged nearby[24]. An overlying limestone of Lower Cretaceous age (Fig. 3) contained algae, bryozoa, corals and echinoderms. Nearby dredge hauls have yielded reefal limestones of Berriasian, Neocomian and Aptian age[24]. The overlying Campanian chalk contains abundant *Stilostomella, Gyroidina, Cibicidoides*, etc., indicating a depth of deposition of at least 1,500 m, while a lower bathyl depth is indicated for the Lower and Upper Palaeocene marly nanno chalks. The Mid-Eocene assemblages suggest site 401 was then at, or close to, its present depth[25].

At site 400A (Fig. 1, Fig. 3), the Aptian planktonic faunas found in the carbonaceous marly chalks are oceanic

Fig. 2 *a*, Location of IPOD–DSDP Leg 48 holes on the south-west Rockall Plateau. *b*, Tracing of multichannel seismic section through sites 403 and 404.



and show evidence of dissolution. The Aptian benthic foraminifera include deep-water species such as *Pleurostomella subnodosa, Gyrodinioides primitiva, Glomospira* sp. and others. The Late Cretaceous fauna has been severely affected by dissolution, and benthic foraminifera are rare though one species, *Aragonia trinitatensis* is a known deep-water form[25]. An abyssal realm of deposition for the Palaeocene claystones and marly chalks is indicated by the benthic foraminifera *Anomalina* sp., *Gavelinella* sp. and *Glomospira gordialis*. The Eocene and Oligocene foraminiferal assemblage is nearly identical to that described from the Oceanic Formation of Barbados and considered to have been deposited in 4–5,000 m depth[26]. Although these data show a progressive increase in depth since Aptian time, quantitative depth inferences are not possible due to poor preservation and the difficulty of assigning precise depth ranges to abyssal benthic faunas. Approximate palaeodepths for the site can be derived, however, from the seismic profiles in the vicinity of sites 400A and 401. These profiles show insignificant post-Aptian faulting, thus indicating that the present 2,000 m of relief between sites 400A and 401 had been created by Aptian time. The relative elevation of the Albian beds at these sites, less a small correction for the Albian palaeodepth at site 401, gives an approximate palaeodepth of site 400A in Albian time of 2,200 m. Using the same method, the Upper Cretaceous and Tertiary palaeodepths of site 401 have been transferred to site 400A and give palaeodepths consistent with the faunal evidence of contemporaneous abyssal depths at site 400A.

The 'Cenomanian' hiatus found at site 400A does not indicate subaerial erosion and uplift, for deep-water Campanian chalks rest directly on deep-water carbonaceous limestones of Albian age without evidence of intra Albian–Campanian faulting (Fig. 1, Fig. 3). At sites 401 and 402A, where the same hiatus is present, subaerial erosion and uplift are again precluded by the absence of post-Albian faulting. The missing Eocene–Lower Cretaceous and Campanian–Lower Cretaceous sections at these sites were either not deposited or were removed by erosion, perhaps by more vigorous bottom currents associated with the 'Cenomanian' transgression.

At Sites 403 and 404 (Fig. 2), on the Rockall Plateau the sequence becomes increasingly clastic downsection. Site 404 bottomed in a conglomerate containing oyster shells that suggests a littoral environment (Fig. 3). The overlying Lower Eocene contains a scarce fauna similar to the Lower Eocene 'London Clay' formation deposited in shallow water. Above 352 m deep-water species were not found, but

abundant plano–convex *Cibicides* indicative of shallow water are present. An upper bathyal depth during the Middle Eocene is suggested by an assemblage of bathyal and upper slope species. During the Late Miocene to the present, lower bathyal depths are indicated by the benthic foraminifera.

Rifting, spreading and subsidence

The subsidence curves given in Fig. 5 describe the depth of the sea floor at the drill sites as a function of age and are compared with theoretical age against depth curves for the Pacific Ocean crust. The curve for site 400A, however, describes the depth of the top of the Aptian as a function of age. The margin subsidence curves have not been isostatically corrected for sediment loading in view of the small sediment thicknesses at each site. In the case of site 403, the isostatically corrected depth is 2,407 m and in the case of site 400A, 4,626 m. These minor corrections further reduce the already small difference in depth between the two sets of curves.

The close similarity of the two sets of curves suggests that these passive margins have thermally subsided with a time constant that may be similar to the 50 Myr exponential time constant deduced for the ocean crust[7,27]. Although the law of subsidence thus seems to be similar, the age-versus-depth relationship for the ocean crust cannot, however, be validly extrapolated to a subsidising passive margin. This is because the absolute depth of a point on a subsiding margin depends on its initial altitude relative to sea level and not on its age, as is the case for the ocean crust. Clearly, points initially above sea level will seem to have subsided less than those below.

In understanding the application of these subsidence curves to passive margins, it is important to distinguish clearly between the thermal régimes of rifting and spreading During rifting, the continental crust is extended but remains joined so that the heat source remains fixed beneath the rift axis. In contrast, during spreading, the heat source migrates away from the passive margins as new crust accretes at the ridge axis. Cooling of the margin can only begin at the end of rifting and the onset of spreading.

If the preceeding discussion is correct, the curves can be used to infer both the onset of spreading and the palaeodepth of the margin at that time. In the case of the Rockall Plateau, extrapolation of the observed curve backward in time and comparison with the theoretical cooling curve suggests initiation of cooling at about 55 Myr. This date closely agrees with the onset of spreading at 52–53 Myr given by the age of the oldest magnetic anomaly[22] recorded in the adjacent ocean crust[21]. The curve also shows that the site was in inner shelf depths at the onset of spreading and cooling.

In the case of the Bay of Biscay, theoretical curves that assume initiation of cooling at 130 Myr for a site at sea level, lie deeper than the curves for sites 401 and 402A and shallower than that for site 400A. The closest correspondence between observed and theoretical curves for site 400A suggests initiation of cooling at about 120 Myr with the site already in 2,000 m depths. Subject to improved palaeobathymetric data, these curves suggest that spreading was initiated in 2,000 m water depths at about 120 Myr in the Bay of Biscay. This conclusion is independently supported by seismic reflection profiles which show that the Albian–Aptian carbonaceous limestones rest on the oceanic crust of the Bay of Biscay.

Although the relationship between subsidence and spreading seems the same for Biscay and Rockall, there are important and unexpected differences in the rifting and post-rifting environments. On the Rockall Plateau, and in Greenland, rifting was associated with volcanism and probably with a substantial subaerial relief, for the first post-rift sediments were deposited in inner shelf conditions at the foot of a 1,000-m scarp close to the continent–ocean boundary (Fig. 2). In Biscay, the Late Jurassic–Early Cretaceous rifting was apparently associated with minor volcanism[12,28] and produced some 2,000 m of submarine relief by the time the first post-rift sediments were laid down. We tentatively suggest that these differences may reflect rifting of an emerged Pre-Cambrian craton in the case of Rockall Plateau and, in the case of Biscay, rifting of an epicontinental Jurassic basin underlain by crust perhaps weakened during earlier Triassic rifting. The results suggest that the subsidence law for passive margins is independent of the structure and initial altitude of the continent and that passive margins begin to subside at the onset of spreading. The subsidence of both margins was accompanied by a gentle oceanward tilt of the margin rather than renewed faulting (Fig. 1, 2). However, the subsidence may have been discontinuous since hiatuses were found on the margins of Biscay and Rockall (Fig. 6). The origin and nature of such hiatuses in both the deep-sea geological record and the adjacent margins is not well understood. The reasonable correlation (Fig. 6) between the hiatuses and/or sedimentation rate changes observed on Biscay and Rockall surely implies the importance of large scale correlative events. In the deep-sea geological record, such events have usually been related to changes in ocean circulation arising from plate reorganisation and/or changes in the sill depths of the ocean basins[30]. In both Biscay and Rockall, increased sedimentation seems to follow spreading rate changes at 55 Myr and 10 Myr, though the correlation is less clear for the Oligocene–Eocene change in spreading. A more surprising correlation seems to exist between these events and unconformities recorded on the adjacent shelf and land (Fig. 6) and associated with uplift[24,31]. If this correlation is real, and validated by further deep-sea drilling, it is important and puzzling for it implies that the continental part of a plate responds vertically in coincidence with changes in spreading rate.

Coupling of hormone receptors to adenylate cyclase of different cells by cell fusion

M. Schramm, J. Orly, S. Eimerl & M. Korner

Department of Biological Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel

A new hormone responsiveness can be conferred on an adenylate cyclase system by coupling it to a foreign hormone receptor. Receptor and enzyme from cells of different species can be compatible with each other.

In recent years, the fusion of different cells has been intensively studied[1-4]. By this process the components of the cell membrane of two different cells could be intermixed[1,5,6]. We have decided to use this phenomenon for the analysis of complex biochemical systems residing in the membrane. Thus, one could test whether a hormone receptor, or enzyme or carrier function is a dissociable unit which can couple to the homologous machinery of another type of cell. Employing the fusion process, we have recently shown that the catecholamine receptor of turkey erythrocytes is able to activiate the adenylate cyclase of mouse erythroleukaemia cells (F cells)[7].

The turkey erythrocytes were first treated with *N*-ethylmaleimide (NEM) or heat to inactivate their adenylate cyclase but not their catecholamine receptor. The F cells possessed an adenylate cyclase but no catecholamine receptor. Fusion of the two cell types with each other by Sendai virus resulted in coupling of the hormone receptor from one cell with the enzyme from the other cell. Inhibitors of protein synthesis had no effect on the process and it was, therefore, concluded that the coupling occurred between pre-existing components.

The experiment established that the catecholamine receptor is a component which is independent of the catalytic adenylate cyclase unit and that the receptor is compatible with the enzyme of another cell. However, the possibility could not be excluded that the catecholamine receptor of the erythrocyte was compatible with the enzyme of the F cell only, because both cells are of erythropoietic origin. There was also no information whether any other hormone receptor could be transferred to a heterologous system.

Present studies show that the *β*-adrenergic receptor can be donated and coupled to heterologous adenylate cyclase systems among a number of cell types of diverse origin and cellular properties. The prostaglandin E1 receptor can also be transferred to adenylate cyclase systems of other cells. Conclusions, with regard to the nature of hormone receptors which couple to adenylate cyclase, are discussed.

Transfer of the β-adrenergic receptor

The NEM-treated erythrocytes (E_{NEM}) bearing the catecholamine receptor, readily and massively fused with mouse adrenal tumour cells (Y-1) (ref. 8). Cell ghosts prepared immediately after fusion, showed a fivefold activation of adenylate cyclase by isoproterenol (Fig. 1). A control fusion of the Y-1 cells among themselves did not produce a catecholamine-responsive system. In addition, binding[18] studies showed that the Y-1 cells contained no measurable amounts of catecholamine receptor. It was concluded that activation by the catecholamine was dependent on the transfer of the receptor from the turkey erythrocytes to the Y-1 cells. In this study, basal activity of adenylate cyclase and activity in presence of fluoride were affected to some extent by the fusion process. However, this did not interfere with interpretation of the experiments since the specific hormonal response is measured as the increase over basal activity. Additional experiments showed that

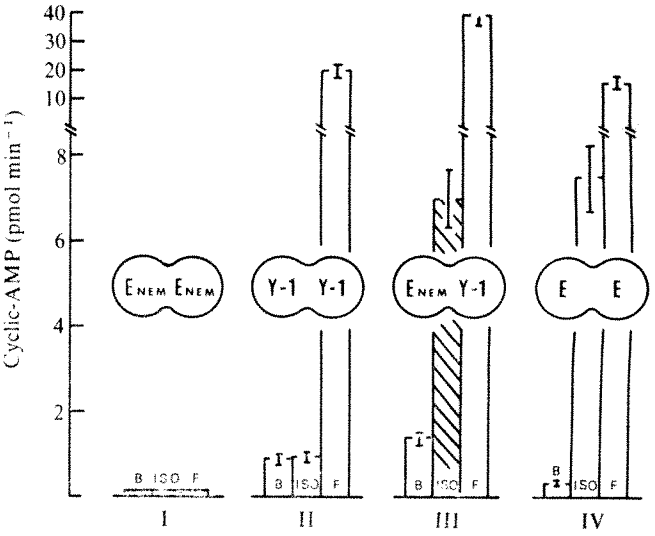

Fig. 1 Coupling of the β-adrenergic receptor of turkey erythrocytes to adenylate cyclase of rat adrenal Y-1 tumor cells by cell fusion. Adenylate cyclase activities are shown for cell ghosts prepared after fusion[7]. Systems were: (I) NEM-treated erythrocytes[7] (E_{NEM}), 3.2×10^8 cells fused with each other; (II) Y-1 cells, 3.0×10^6 fused with each other; (III) heterologous fusion of E_{NEM} cells, 3.2×10^8 with Y-1 cells, 3.0×10^6; (IV) untreated erythrocytes (E), 3.2×10^8 fused with each other. The cell types which participate in fusion are symbolised in the figure by fused circles in each set of columns. At the base of each column the activating agent is specified: B, basal activity in the presence of 20 μM propranolol; ISO, 50 μM isoproterenol; F, 10 mM fluoride. Bars at the top of the column show the range of activities of duplicate fusion systems. The response of the hormone receptor transferred by fusion to a heterologous system is emphasised by a hatched column. Adenylate cyclase activity[9] shown was measured in duplicate on cell ghosts equivalent to 1/7 of the cells in the fusion system. Y-1 cells (ATCC) were grown in Roux bottles and were subcultured as described[8]. Cells from confluent cultures (5–10 d) were suspended as follows; the monolayers of cells were washed with phosphate-buffered saline (PBS) *p*H 7.5 (140 mM NaCl, 20 mM KCl 10 mM KH_2PO_4). Two ml of PBS containing trypsin, 0.01% (w/v) (Worthington 2×crystallised and lyophylised) chymotrypsin, 0.01% (w/v) (Sigma 3×crystallised) and EDTA, 0.7 mM were placed on the cultures. After incubation for 3–5 min at 37 °C, trypsinisation was terminated by addition of 10 ml growth medium containing Soybean trypsin inhibitor (STI), 1 mg ml⁻¹. The cells were washed twice in Na^+ salt medium[7] and resuspended for fusion in Na^+ salt medium containing STI (0.5 mg ml⁻¹). Turkey erythrocytes were prepared for fusion as previously described[7]. The procedure for fusion by Sendai virus was adapted[7] from that of Loyter *et al.*[4]. Sendai virus was produced[10] by Dr Loyter of this department. The amount of virus was 3,000 HAU in systems I, III, IV and 2,000 HAU in system II. Progress of fusion was followed by phase contrast microscopy. After 45 min at 37 °C when most of the Y-1 cells were fused with erythrocytes, the cells were transferred to ice and cell ghosts were prepared by hypotonic lysis[7]. Experiments were repeated at least three times.

C6 (BU1) rat glioma cells[11,12] treated with NEM readily transferred their catecholamine receptor to F cells (Fig. 2). These findings showed that neither the erythrocytes nor the F cells used in our previous work are unique partners for the coupling experiment. A successful matching of the β-adrenergic receptor of C6 cells with the adenylate cyclase of Y-1 cells was therefore predicted and demonstrated (Fig. 3). The presence of protein synthesis inhibitors before and during Y-1 self fusion had no effect on transfer of the β-adrenergic receptor. It is, therefore, obvious that the coupling occurred between pre-existing components.

The question whether the affinity of the β-adrenergic receptor for agonists is affected by the milieu in which it operates is of considerable interest[13,14]. The ability to couple the receptor to an adenylate cyclase of another cell presented a unique opportunity to submit the problem to actual testing. It is shown in Table 1 that the dissociation constants for adrenaline, noradrenaline and propranolol do not change significantly when the β-adrenergic receptor of the erythrocytes becomes coupled to the adenylate cyclase of F cells or Y-1 cells. It is particularly noteworthy that the ratio of dissociation constants for noradrenaline–adrenaline, which serves to distinguish various types of β-adrenergic receptors[15], remains essentially unchanged.

In a further experiment rat hepatoma cells (HTC) which have no adenylate cyclase activity[16] produced a response to isoproterenol when fused with F cells. Stimulation of adenylate cyclase over basal activity was only 1.8-fold but was consistently obtained in three independent experiments (data not shown). Surprisingly, this indicates that a receptor without apparent function had been preserved throughout many months of growth of the HTC cells in suspension culture. A selected variant of HTC, grown in stationary culture, has recently been shown to bind a β-adrenergic antagonist[17].

Transfer of the prostaglandin E1 receptor

The experiments on the β-adrenergic receptor suggested that perhaps other hormone receptors could also be transferred from one adenylate cyclase system to another. Since the F cell showed strong activation of its adenylate cyclase by PGE$_1$, transfer of the PGE$_1$ receptor was attempted. Figure 4*a* shows that the adenylate cyclase system of Y-1 cells can be efficiently coupled to the PGE$_1$ receptor of NEM-treated F cells. As a control, activation of adenylate cyclase by PGE$_1$ was also tested on Y-1 cells fused with C6 cells (system III of Fig. 3 served in the test). PGE$_1$ did not increase enzyme activity of the fused preparation. Therefore, the response cannot be due to unmasking of a receptor in Y-1 by fusion *per se* with a different cell. The PGE$_1$ receptor could also be contributed by F cells which had been heat treated to inactivate the adenylate cyclase (Fig. 4*b*). Thus such experiments are not exclusively dependent on the inactivation by NEM. Fusion of the heat treated cells with each other or with HTC cells did not reactivate the adenylate cyclase. The latter is a particularly important control since HTC cells are vigorously growing though they lack adenylate cyclase activity[16]. HTC cells also did not reactivate NEM-treated F cells or NEM-treated C6 cells which were used in experiments of this study. It is also of interest that the PGE$_1$ receptor and the β-adrenergic receptor[7] are both more heat resistant than the adenylate cyclase to which

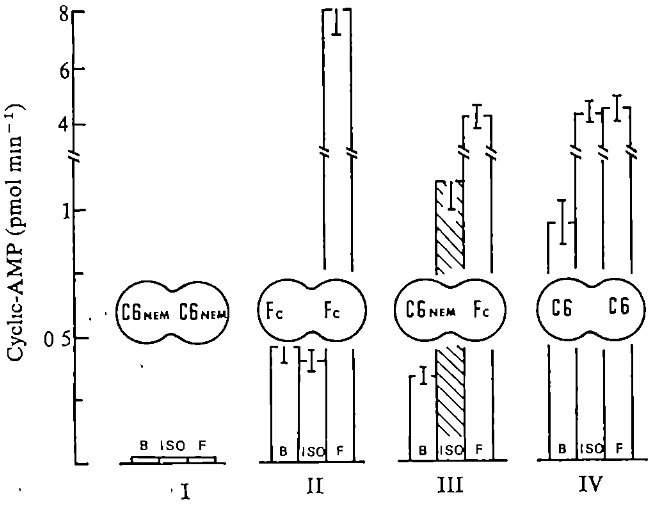

Fig. 2 Coupling of the β-adrenergic receptor of rat glioma cells (C6) with adenylate cyclase of Friend erythroleukaemia (Fc) cells. Systems were: (i) NEM-treated C6 cells ($C6_{NEM}$), 1.5×10^6, fused with each other; (ii) F cells, 1.2×10^6 fused with each other; (iii) heterologous fusion between $C6_{NEM}$ cells, 1.5×10^6 and F cells, 1.2×10^6; (iv) untreated C6 cells, 1.5×10^6, fused with each other. Other details are as in Fig. 1. F cells were grown and collected for fusion as previously described[7]. C6 cells were grown and collected for fusion as described for Y-1 cells in Fig. 1. (The culture was given by Dr U. Bachrach of this university.) The amount of virus was 400 HAU in systems i, iii and 200 HAU in ii and iv. After 22 min at 37 °C the systems were transferred to the cold and cell ghosts were prepared by hypotonic lysis.

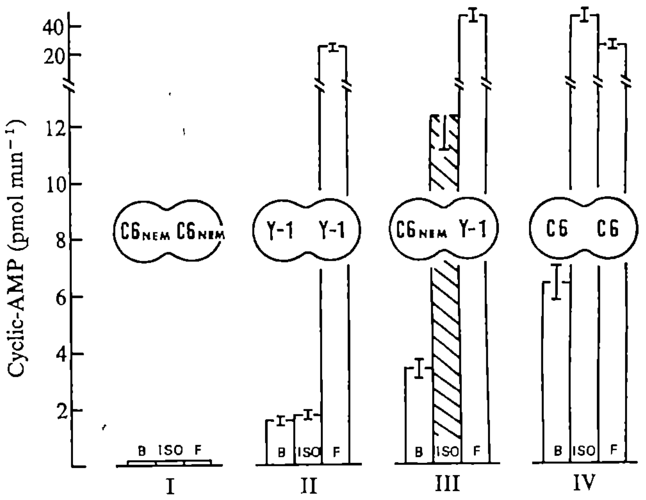

Fig. 3 Coupling of the β-adrenergic receptor of C6 cells with adenylate cyclase of Y-1 cells. Systems were: (i) $C6_{NEM}$, 1.2×10^7 fused with each other; (ii) Y-1 cells, 2.7×10^7 fused with each other; (iii) heterologous fusion between $C6_{NEM}$ cells, 1.2×10^7 and Y-1 cells, 2.7×10^6; (iv) untreated C6 cells, 1.2×10^7 fused with each other. The amount of virus was 400 HAU in systems i, ii, iv and 80 HAU in system ii. After 28 min at 37 °C the systems were placed on ice and cell ghosts were prepared. Other details are as in Fig. 1. Essentially the same results were obtained in a different experiment carried out in the presence of protein synthesis inhibitors: 15 min before fusion all cell suspensions received emetine, 20 μM and cycloheximide, 20 μM. The inhibitors remained present during fusion.

Table 1 Conservation of affinities of the β-adrenergic receptor after transfer to a heterologous adenylate cyclase system*

Cells in fusion	Apparent dissociation constants		dl-propranolol
	l-Adrenaline μM	l-Noradrenaline μM	nM
E	2.0	1.6	11
E_{NEM}–Y-1	1.8	1.1	9
E_{NEM}–Fc	1.5	1.0	—

*Fusion systems were prepared as described in legend of Fig. 1. Adenylate cyclase activities were determined on the cell ghosts in the presence of various hormone concentrations and the constants were calculated from a Lineweaver–Burk plot. Various amounts of l-epinephrine were added to 0.1 μM propranolol to determine the dissociation constant of the blocker.

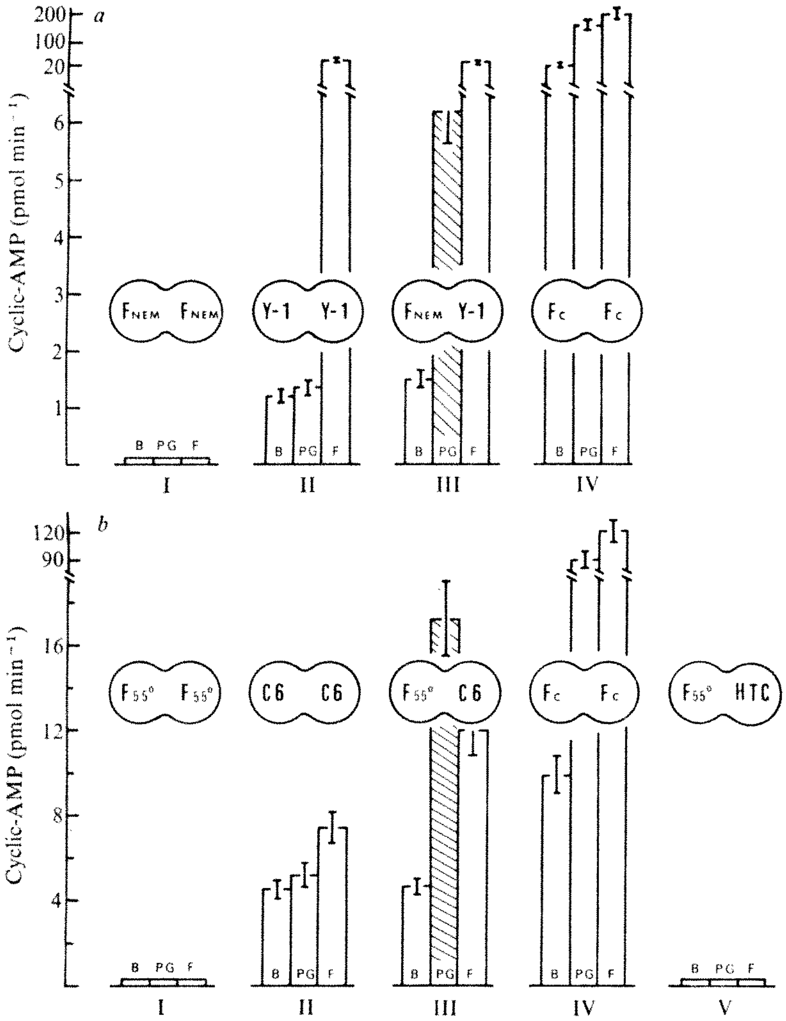

Fig. 4 Coupling of the prostaglandin E_1 receptor of F cells to adenylate cyclase of other cells. *a*, NEM-treated F cells (F_{NEM}) fused with Y-1 cells, systems were: (i) F_{NEM}, 1.3×10^7 fused with each other; (ii) Y-1 cells, 2.3×10^6 fused with each other; (iii) heterologous fusion between F_{NEM} cells, 1.3×10^7 and Y-1 cells, 2.3×10^6; (iv) untreated Fc cells, 1.3×10^7 fused with each other. Other details are as in Fig. 1, except that the hormone was prostaglandin E_1 (PG) 10 μM (given by Dr J. Pike, Upjohn Co., USA). The amount of virus was 400 HAU in systems i, iii, iv and 200 HAU in system ii. After 14 min incubation at 37 °C systems were placed on ice and cell ghosts were prepared by mild sonication[17]. Cells were sedimented by centrifugation for 3 min at 200*g* and the pellet was suspended in 0.35 ml of Na^+ salt medium containing 3 mM β-mercaptoethanol and 0.5 mg ml^{-1} STI. The cell suspension was sonicated for 15 s in a bath sonicator (Laboratory Supplies Co., Model T-80-80-1). *b*, Heat-treated F cells ($F_{55°}$) fused with C6 cells systems were: (i) $F_{55°}$ 1.2×10^7 fused with each other; (ii) C6 cells, 3×10^6 fused with each other; (iii) heterologous fusion between heated F cells, 1.2×10^7 and C6 cells, 3×10^6; (iv) F cells, 1.2×10^7 fused with each other; (v) heterologous fusion between heated F cells, 1.2×10^6 and HTC cells, 2.5×10^6. HTC cells were grown in suspension[19] and supplied by Dr R. Kulka of this department. F cells were suspended in 1.6 ml of Na^+ salt medium in a glass test tube to give 6×10^7 cells ml^{-1}. The cells were heated at 55 °C for 4 min and cooled in ice. Damage to the cells by the heat treatment was not visible by phase contrast microscopy. The amount of virus was 500 HAU in systems i, iii, iv, v and 100 HAU in system ii. After 15 min at 37 °C the fused cells were transferred to the cold and sonicated as described in Fig. 4*a*. Other details as in Fig. 1.

they were originally coupled. The PGE_1 receptor of NEM-treated F cells was also transferred to adenylate cyclase of C6 cells. PGE_1 increased enzyme activity 3.7-fold in the fused membranes (data not shown).

Experiments are in progress to transfer the ACTH receptor of the Y-1 cells to other cell types. Adenylate cyclase stimulation by ACTH in the strain of Y-1 cells used has, however, so far been rather weak and variable.

Experimental techniques

The coupling of a hormone receptor from one cell with the adenylate cyclase of another cell by the procedure described, is based on several essential requirements. Means and conditions for massive fusion must be provided because the transfer of receptor will only be evident if a considerable amount of the total adenylate cyclase in the system has been joined by the heterologous receptor. With cells having a high basal activity of adenylate cyclase, it may be difficult to demonstrate significant hormonal stimulation by coupling to a heterologous receptor. When using Sendai virus as a fusing agent the amount of virus must be accurately titrated. Both excess virus and prolonged incubation after fusion cause severe lysis of cells and inactivation of adenylate cyclase. The age and growth conditions of the cells used is also critical. For instance, adenylate cyclase in young cultures of C6 shows little response to catecholamine[20]. F cells in the stationary phase were unsuitable for heat or NEM treatment since they underwent lysis during fusion or failed to fuse. In fact, it has been our routine observation that NEM- or heat-treated cells fuse less efficiently with each other as compared with their heterologous fusion with native untreated cells. However, in turkey erythrocytes NEM treatment encouraged fusion. It is difficult to distinguish heterologous from homologous fusion when the partners are of similar appearance under the phase contrast microscope (C6, Fc and Y-1). Since NEM-treated cells fuse less readily with each other, counting the percentage of unfused cells serves as a rough indication of the extent of heterologous fusion.

Receptor–enzyme matching

It is obvious from our past[7] and present data that matching of a receptor to a heterologous adenylate cyclase system readily occurs with a considerable variety of cells of different origin, type of differentiation and method of growth. As yet, we have not encountered a fusible cell type which failed to serve in heterologous receptor–enzyme matching. Blood cells, cells grown in suspension or cells grown in monolayer and subsequently suspended by trypsinisation served equally well. The fact that the cells already possessed one native receptor (PGE_1 in F cells, ACTH in Y-1 cells, β-adrenergic in C6 cells) did not prevent acceptance of an additional transferred receptor. The same cell could contribute the adenylate cyclase, in coupling with a foreign receptor, or contribute the receptor in coupling with a foreign adenylate cyclase ($Fc–C6_{NEM}$, $F_{NEM}–C6$). These observations considerably broaden our recent conclusion[7] that the receptor is a unit independent of the enzyme and allows some suggestions as to the nature of the different hormone receptors. The unhindered transfer of two different receptors to adenylate cyclase systems of several cells suggests that the mechanism of coupling between receptors and adenylate cyclase may be universal for all eukaryotic cells. The change that must occur in the receptor upon binding of the specific hormone, which results in activation of the enzyme, is probably also identical for all these hormone receptors. Thus, it is likely that all hormone receptors which couple to adenylate cyclase have a common chemical structure, differing only in the confined area which binds the specific hormone. Because of these considerations it is expected that when hormone receptors will become available as purified proteins, it will be possible to implant them in the adenylate cyclase systems of many eukaryotic cells.

More immediate application of the technique could be to determine why OS3 and Y-6 adrenal tumour cells fail to respond to ACTH with adenylate cyclase activation[21,22] and to test for 'silent' receptors[7] as apparently demonstrated for the β-adrenergic receptor of HTC cells. It would also be interesting to see whether the β-adrenergic receptor from a unicellular organism (such as *Tetrahymena*[23]) is compatible with the adenylate cyclase of primates.

We thank Mrs N. Zakai and Dr A. Loyter for much advice about cell fusion and for supply of Sendai virus. The work was supported by grants from the National Institutes of Health, USA, and the U.S.–Israel Binational Science Foundation. M.S. is an established investigator of the Israel Ministry of Health.

Self-assembly and catalytic activity of the pyruvate dehydrogenase multienzyme complex of *Escherichia coli*

David L. Bates*, Michael J. Danson, Geoffrey Hale, Elizabeth A. Hooper & Richard N. Perham

Department of Biochemistry, University of Cambridge, Tennis Court Road, Cambridge, UK

Studies of the self-assembly of pyruvate dehydrogenase of Escherichia coli *show that the catalytic activity is proportional to the state of assembly and uncover a novel functional connection of active sites in this multienzyme complex.*

THE pyruvate dehydrogenase multienzyme complex of *Escherichia coli*[1,2] catalyses the overall reaction

$$\text{Pyruvate} + \text{NAD}^+ + \text{CoA} \rightarrow \text{Acetyl-CoA} + \text{NADH} + \text{H}^+ + \text{CO}_2$$

The complex, which is somewhat larger than a ribosome, is composed of multiple copies of three different types of polypeptide chain, responsible for the three constituent enzymic activities: pyruvate decarboxylase (E1) [EC 1.2.4.1], lipoate acetyltransferase (E2) [EC 2.3.1.12] and lipoamide dehydrogenase (E3) [EC 1.6.4.3]. The commonly accepted mechanism is outlined in Fig. 1.

The complex can be taken apart and the component enzymes reassembled *in vitro* to form the original structure[3] and since enzymes E1 and E3 do not associate with each other in the absence of enzyme E2, it is clear that the latter forms the structural core of the assembled complex. It is probable that enzyme E2, like the corresponding lipoate succinyltransferase from the 2-oxoglutarate dehydrogenase complex, has octahedral (432) symmetry[4], which implies that it is composed of 24 polypeptide chains[2,4]. These arguments from X-ray diffraction and electron microscopy[2,5] apparently dispose of an alternative model in which E2 comprises 16 polypeptide chains[6]. On the other hand, two conflicting versions of the number of polypeptide chains in the intact complex are current. It has been proposed[7,8] that there are about 24 chains of E1, 24 chains of E2 and about 12 chains of E3 whereas other measurements[6,9] indicate that the complex generally carries a molar excess of E1 chains, the polypeptide chain stoichiometry (E1 : E2 : E3) having an upper limit of 2 : 1 : 1 (refs 9, 10).

Three active sites in three different component enzymes participate in the overall reaction (Fig. 1). The substrate is borne by a lipoic acid residue which is covalently linked through its carboxyl group to the N^6-amino group of a lysine residue in each chain of the E2 component[11]. The lipoyl-lysine 'swinging-arm' is postulated to rotate among the catalytic centres of the three enzymes[3,12] and a study of the electron spin resonance spectra of spin-labelled lipoamide residues has provided the first convincing physicochemical evidence consistent with this hypothesis[13,27]. But, modifications to the simple reaction mechanism presented in Fig. 1 must be envisaged since we now know that each E2 chain bears not one but two functionally active lipoyl residues[14].

In this article we describe two new sets of experiments. We examine the self-assembly of the enzyme complex from the separated E1 component and E2-E3 subcomplex. We show that the chain ratio E1 : E2 reaches a limiting value of 2 : 1 and that catalytic activity in the overall reaction is proportional to the state of assembly of the complex. We go on to examine the

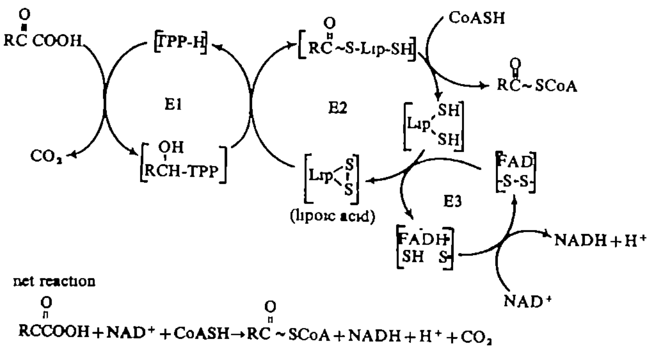

Fig. 1 The reaction mechanism of the pyruvate dehydrogenase multienzyme complex of *E. coli*. E1 (pyruvate decarboxylase, EC 1.2.4.1), E2 (lipoate acetyltransferase, EC 2.3.1.12) and E3 (lipoamide dehydrogenase, EC 1.6.4.3) represent the three enzymic activities that make up the complex. TPP-H, thiamin pyrophosphate.

fate of substrate within the complex and demonstrate participation of the lipoyl-lysine swinging-arms in subunit interactions of a novel and hitherto unsuspected kind.

Self-assembly and catalytic activity

Pyruvate dehydrogenase complex was prepared by the method of Reed and Mukherjee[15] from a strain of *E. coli* K12 constitutive for the enzyme (provided by Professor H. L. Kornberg). The complex was dissociated into free E1 and E2–E3 subcomplex at *p*H 10 and these were resolved by gel filtration on a column of Sepharose 6B (refs 16, 17). The concentrations of the resultant stock solutions were determined by amino acid analysis[18]. The polypeptide chain stoichiometry (E1: E2: E3) of the E2–E3 subcomplex was found to be 0.06: 1.0: 0.88 by means of the radio-amidination method of Bates *et al.*[9]. The E1 component gave the single band expected on sodium dodecylsulphate (SDS)–polyacrylamide gel electrophoresis. A series of partly reassembled complexes was then prepared by adding increasing amounts of E1 to a constant amount (0.29 mg) of E2–E3 subcomplex in 50 mM sodium phosphate buffer, *p*H 7.0. Each mixture was held for at least 10 h at 0 °C and any unbound E1 was then separated from assembled complex by gel filtration on Sepharose 6B. Initially, all the E1 added became bound and a single high molecular weight species emerged from the Sepharose column. But, when the amount of E1 in the assembly mixture reached 0.41 mg, free E1 component began to appear in the low molecular weight region of the column eluate and thereafter any additional E1 was found in this peak. As judged by SDS–polyacrylamide gel electrophoresis and by enzyme assay[14] of the column eluates, no E3 was displaced from the complex during the assembly.

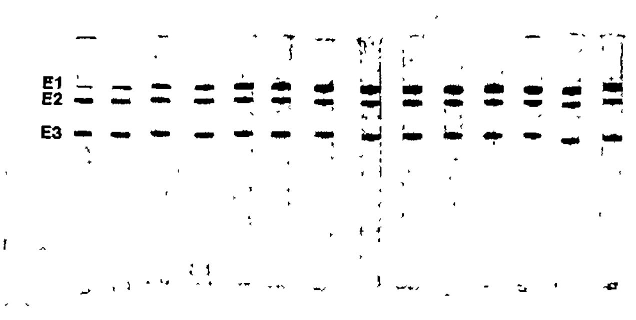

Fig. 2 Analysis by SDS–polyacrylamide gel electrophoresis of the self-assembly of the pyruvate dehydrogenase multienzyme complex. A series of partly reassembled complexes was prepared by adding increasing amounts of E1 to a constant amount (0.29 mg) of E2–E3 subcomplex in 50 mM sodium phosphate buffer, *p*H 7.0, containing 2 mM EDTA and 1 mM sodium azide. The protein concentrations were determined by amino acid analysis. After 10 h at 0 °C, the mixtures were gel filtered on a column (650 × 6.5 mm) of Sepharose 6B in the same buffer, and the fractions containing the complex were pooled. Samples were submitted to SDS–polyacrylamide gel electrophoresis in standard conditions[19] and the gels correspond, from left to right, with the points plotted in Fig. 3. The subunit molecular weights are: E1, 100,000; E2, 80,000 and E3, 56,000 (refs 6, 19).

Analysis of the series of partly reassembled complexes by SDS–polyacrylamide gel electrophoresis is shown in Fig. 2. An upper limit to the binding of E1 was quite clear, without apparent displacement of E3. A sample (about 0.25 mg) of each complex was also analysed by the radio-amidination method[9] to determine the polypeptide chain stoichiometries, which are presented in Fig. 3. These chain ratios are plotted against the molar ratio of E1 : E2 chains in the assembly mixture before gel filtration. The binding of E1 to the E2–E3 subcomplex is evidently very tight. The subcomplex is apparently saturated when 1.8 chains of E1 are bound per chain of E2, as measured by the amidination assay of the assembled complexes. This result is supported by the observation (Fig. 3) that complete assembly and activity were only reached when the molar ratio of E1 : E2 chains (the latter as subcomplex) in the assembly mixture was 2 : 1, as measured by amino acid analysis. We estimate that the binding constant for E1 to the E2–E3 subcomplex must be in excess of 10^7 M^{-1} to account for the shape of the curve in Fig. 3. The E3 content of the series was constant at a mean value of 0.85 chains per chain of E2, which does not differ significantly from the value of 0.88 in the starting subcomplex. This experiment fully supports our suggestions that the limiting polypeptide chain stoichiometry is 2 : 1 : 1 (refs 9, 10).

The E3 activity of the complex (that is, the reduction of NAD^+ by exogenous dihydrolipoamide) is unaffected by the binding of E1, as was shown by assaying a sample of E2–E3 subcomplex for this activity in the presence of increasing amounts of E1. Since the E2: E3 chain ratio for the series of reassembled complexes was constant, we could therefore use the E3 activity as a measure of the amount of subcomplex in each species. Thus we could determine how the overall pyruvate dehydrogenase activity varied with the E1 content of the complex. Accordingly, the overall complex and E3 activities of the partly assembled enzyme complexes were measured using standard assays[14] and the ratios of these activities are also plotted in Fig. 3. The increase in overall complex activity closely followed the binding of E1, maximum activity being reached only when the subcomplex had bound its full complement of E1 chains. The effective specific activity of the E1 component in the complex was therefore at least approximately constant.

Reaction mechanism and the interaction of active sites

We had previously shown that each E2 chain bears two functionally active lipoic acid residues[14]. We have now demonstrated that the maximal overall complex activity is achieved when the limiting chain stoichiometry (E1 : E2) of 2 : 1 is reached (Fig. 3). The free E1 component is thought to be a dimer[7,20] although it seems to dissociate at high *p*H into monomers[10,21]. Only the dimer is catalytically active[21]. The simplest formulation of the generally accepted mechanism (Fig. 1) would envisage direct transfer of substrate through a fixed geometric arrangement of three active sites. This proposition was tested as follows.

In the presence of the substrate 2-^{14}C-pyruvate, and the absence of CoA, the lipoic acid residues of the complex become acetylated and reaction then ceases (Fig. 1). The extent of acetylation can be measured by counting the radioactivity in samples of the complex after precipitation with trichloroacetic acid and this can then be correlated with the E1 content of the complex. A new series of partly reassembled complexes was therefore prepared as described above, except that the proportions of E1 and E2–E3 subcomplex in the assembly mixture were chosen to yield some complexes with lower E1 : E2 ratios. The ratios were then measured by the radio-amidination method[9]. Samples (each containing about 15 µg of E2–E3 subcomplex) of the partly reassembled complexes were incubated at *p*H 7.0 with 0.2 mM 2-^{14}C-pyruvate in the absence of CoA and, after 2 min, the protein was precipitated with trichloroacetic acid and counted for radioactivity. The radioactivity incorporated was plotted against the E1 : E2 chain ratio (Fig. 4): as in the previous experiment, the measured E2 : E3 chain ratio and the E3 enzymic activity were used to normalise the results to the same constant amount of E2. The maximum extent of acetylation was calculated from the specific radioactivity of the 2-^{14}C-pyruvate to be approximately two acetyl groups bound per E2 chain, in good agreement with our previous measurements of the lipoic acid content of the complex by other means[14]. It is clear from Fig. 4 that the extent of acetylation of lipoic acid residues on the E2 chains rose initially much more steeply than the E1 : E2 chain ratios of the complexes, implying that more than one E2 chain was 'serviced' by a given E1-dimer in the complex. A simple 1 : 1 correspondence of E1 chains bound with lipoic acid residues acetylated is obviously excluded.

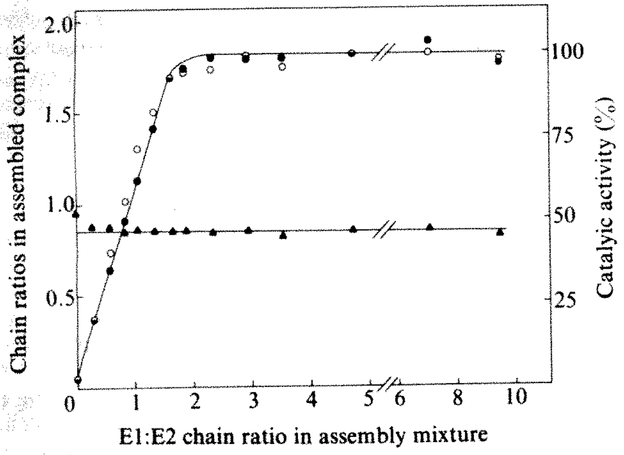

Fig. 3 The polypeptide chain stoichiometries and catalytic activities of the series of partly reassembled complexes described in Fig. 2. The polypeptide chain ratios, measured by radio-amidination[9], are based on E2 as unity. These ratios (E1, ●; E3, ▲) are plotted against the chain ratios of E1:E2 (the latter as subcomplex) in the assembly mixtures before gel filtration, as determined by amino acid analysis of the stock solutions. Five SDS gels were run for each sample and the maximum standard deviation encountered was 6%. A least-squares analysis of the first seven points gave a gradient of 0.99 and we estimate a minimum equilibrium constant of 10^7 M^{-1} for the binding of E1 to the E2–E3 subcomplex. The ratio of the overall complex activity[14] to that of the E3 component[14] for each sample is also plotted (○). The final value reached was 0.66 (compared with 0.7 in the complex before resolution) and the maximum overall complex activity recovered was 25 IU per mg, the same as the complex before resolution.

The binding of E1 to the E2–E3 subcomplex is non-cooperative and the binding sites can be assumed to be identical (ref. 10 and unpublished work of W. Busch and U. Henning, quoted in ref. 25). Let us suppose that n E2-chains can be serviced by a single E1-dimer and conversely, therefore, that a given E2-chain can be acetylated by the action of any of n different E1-dimers. Let p be the ratio of E1 dimers to E2 polypeptide chains in a given complex. Then the probability that an E1 binding site is occupied is also p. If there is one binding site for an E1-dimer on each E2 chain, which is implied by the maximum polypeptide stoichiometry of 2 : 1, then the probability that an E2 chain will not be acetylated is the same as the probability that n E1-dimers will not be bound, which is $(1-p)^n$. Thus the probability, f, that an E2 chain will be acetylated is

$$f = 1-(1-p)^n \qquad (1)$$

In the experiment, we have measured f as a function of the E1 : E2 polypeptide chain ratio, r. But $r = 2p$, so

$$f = 1-(1-r/2)^n \qquad (2)$$

This equation describes the curves which have been plotted for various integral values of n in Fig. 4. The experimental points lie closest to the line described by $n = 12$.

Rearrangement of equation (2) gives

$$\log(1-f) = n \log(1-r/2) \qquad (3)$$

Replotting the experimental data from Fig. 4 in this form gives a good straight line of gradient, $n = 12 \pm 1$.

It should be noted that the form of the curves in Fig. 4 does not depend on the assumption that E1 is active only as dimers. Identical theoretical lines are obtained if random binding of active monomers to two sites on E2 is taking place. The value of n corresponding to any curve would then be halved since it would refer to the number of E2 chains whose acetylation is caused by a monomer of E1.

In the 'servicing' experiments we have described above, the enzyme complexes were incubated with 2-^{14}C-pyruvate for 2 min before being precipitated with trichloroacetic acid. But, the same extent of acetylation was observed when the incubation time was reduced to 20 s.

Symmetry and transacetylation within the complex

The most plausible model for the structure of the E2 core of the multienzyme complex takes the form of a cube with

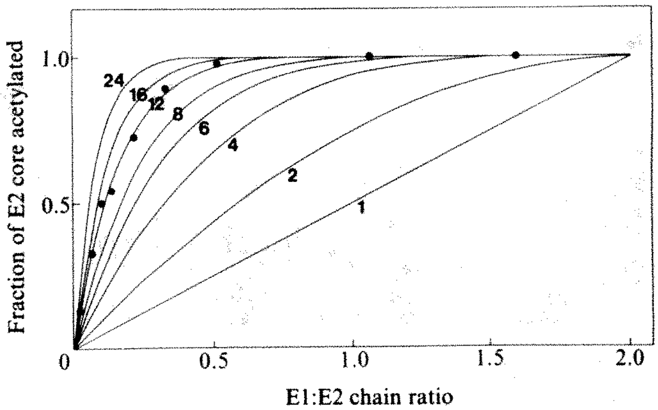

Fig. 4 Acetylation with 2-^{14}C-pyruvate of the E2 component of a series of partly reassembled pyruvate dehydrogenase multienzyme complexes. Samples of pyruvate dehydrogenase complex were incubated at 0 °C with 0.2 mM 2-^{14}C-pyruvate in 0.1 ml of 50 mM sodium phosphate buffer, *p*H 7.0, containing 0.7 mM thiamin pyrophosphate, 10 mM $MgCl_2$ and 1 mM NAD^+. After 2 min, 50 µl of rabbit immunoglobulin G (Mann Research: 20 mg ml^{-1} in 20 mM sodium phosphate buffer, *p*H 7.0) was added as carrier protein, followed immediately by 1 ml of ice-cold 12.5% trichloroacetic acid. The precipitated proteins were collected on glass microfibre filters (Whatman GF/C) and were washed with 25 ml of 12.5% trichloroacetic acid, 6 ml of acetone containing 50 mM HCl and finally 6 ml of diethyl ether. The dry filters were placed in vials with 4 ml of toluene containing 2,5-diphenyloxazole (5 gl^{-1}) and counted for radioactivity in a Nuclear Chicago Unilux II-A scintillation counter[22]. The stoichiometries of the polypeptide chains in the pyruvate dehydrogenase complexes were determined by radio-amidination[9]. The theoretical curves are plotted from the equation $f = 1-(1-r/2)^n$, for integral values of n as shown, where f = fraction of the E2 core acetylated, r = chain ratio of E1:E2 and n = number of E2 chains acetylated by the action of one E1-dimer.

octahedral symmetry, comprising 24 polypeptide chains[2,4]. It is clear from our experiments that *n* does not have the minimum value of 1 nor the potential maximum value of 24. One E1 dimer is not able to cause the acetylation of the whole E2 core. It would be expected *a priori*, however, that the observed value of *n* would be a multiple of one or more of the symmetry elements. For the octahedral model, *n* could have the values 1, 2, 3, 4, 6, 8, 12 or 24. Our present value of 12 can therefore be reconciled in principle with octahedral symmetry.

The possibility that one E1 dimer can interact direct with all 12 susceptible E2 chains simultaneously is discounted in view of the very large distances that would have to be spanned between the active sites (the complex is at least 30 nm in diameter[1,2,23]), compared with the length (1.4 nm) of the lipoyl-lysine swinging arm. Similarly, rapid migration of the E1 dimer from one binding site to another can be ruled out since an answer of $n = 24$ would be expected if the binding sites remained equivalent. We are left with the possibility that acetyl groups can be transferred between lipoyl residues bound to neighbouring E2 chains in the core, a reaction we shall term 'transacetylation' and which should be distinguished from the transfer of acetyl groups to CoA to form product (Fig. 1). The diameter of a globular E2 polypeptide chain (molecular weight 80,000; refs 19, 24) would be of the order of 6 nm, and we know that there are two lipoyl-lysine swinging arms of length 1.4 nm each per E2 chain[14], giving a potential total span of at least 5 nm for each subunit. Conformational changes in the complex might also facilitate transacetylation, so this mechanism seems structurally feasible.

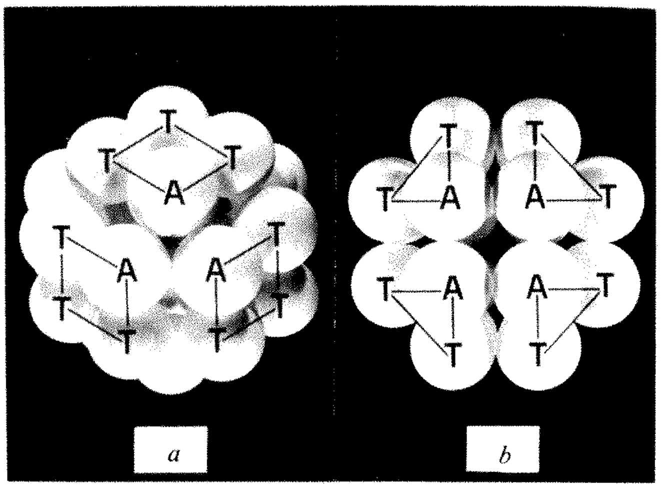

Fig. 5 Two models for the mechanism of acetylation of 12 E2 chains by means of a single E1-dimer in the pyruvate dehydrogenase multienzyme complex. The views are along (*a*), threefold and (*b*), fourfold axes of the E2 core component. The subunits acetylated by direct physical interaction with a single E1-dimer are marked with an A. Those acetylated by subsequent transacylation are marked with a T and shown linked to the appropriate subunit of type A. The total number of chains acetylated in either model is 12.

If the postulated transacetylation reactions could take place between each and every subunit in the E2 core, *n* would obviously have the value 24. To limit it to 12, we must therefore restrict the transacetylation in some way. One possible model of the E2 core with octahedral symmetry is shown in Fig. 5. Every E2 chain can be regarded as one of the three subunits in a trimer cluster at each of the eight corners of the cube or as one of the four subunits arranged about the fourfold axis on each of the six faces of the cube. We propose two possible reaction schemes. Consider a single E1 dimer bound to any one E2 chain. This E1 dimer might cause the independent acetylation of all three E2 chains in the trimer cluster at a corner of the cube by direct reaction, which would be followed by transacetylation among the four chains on each of the three cognate faces of the cube (Fig. 5*a*). Alternatively, the E1 dimer might cause the independent acetylation of four E2 chains by direct reaction with each of the subunits on a fourfold axis on the face of the cube, which would be followed by transacetylation among the three chains in the trimer clusters at each of the four corners of that face (Fig. 5*b*). We cannot for the moment choose between these two schemes but in both we must postulate that the subunits that become acetylated by direct reaction with the E1 dimer cannot engage in rapid transacetylation reactions among themselves.

Conclusions

Our results on the stoichiometry of polypeptide chains in the self-assembly of the complex substantiate our previous work[9,10] and are in good agreement with the chain ratios of the native complexes isolated by Vogel *et al.*[6] except that the highest value they recorded for the E1 : E2 chain ratio was 1.4. From our measurements of subunit stoichiometries and assuming octahedral symmetry for the E2 component, we would predict a molecular weight of about 8×10^6 for the fully assembled complex. This molecular weight predicted from symmetry arguments and protein chemistry has since been found to be in very good agreement with that measured independently by ultracentrifugation methods (M.J.D. and A. J. Rowe, unpublished).

The discovery of extensive internal transacetylation reactions in the complex has revealed a novel system of functional connection of active sites. The value of $n = 12$ gives a good fit of theory to experiment (Fig. 4) and, even if we are wrong in detail, *n* must clearly be very much greater than 1, the value implicit in the usual formulation of the mechanism (Fig. 1). Quenched-stopped-flow experiments[26] suggest that the transacetylation reactions are sufficiently fast to be kinetically competent in the normal enzymic reaction (M.J.D., A. R. Fersht and R.N.P., unpublished). They form a way of 'posting' acetyl groups and associated reduction of lipoyl residues from an E1 site to a physically distant E3 site. What advantage, if any, they confer may become apparent when the reaction is dissected in further detail.

We are grateful to the SRC, ICI and the Wellcome Trust for financial support. We thank Dr K. Sargeant and Mr A. R. Whitaker, Microbiological Research Establishment, Porton Down, for growing the bacteria.

letters to nature

NP0532 and a hole in the Crab Nebula

THE Crab Nebula may account for as much as 35% of the dispersion measure, D, of its pulsar, NP0532 (ref. 1). Davidson and Terzian[1] have pointed out that if this is so, and if the ionised material is distributed uniformly over the volume of the nebula, then the Crab's expansion[2] of ~ 1,000 km s^{-1} should cause a decrease in D of about 0.07% per year. Isaacman and Rankin[3] studied the dispersion measure over a 5-yr period, however, and observed no such decrease. From this, an upper limit to the Crab's contribution to D can be derived. It is much smaller than previously suspected.

The variability of D is illustrated in Fig. 1; there is no secular decrease and there is a 2-yr long linear rise beginning in mid-1972. The fractional increase, to mid-1974, is about 0.1%. The times of elevated dispersion measure—from August 1969 through May 1971, and from July 1972 onward—probably occur when the line of sight is interrupted by a turbulence cell of enhanced electron density in either the Crab Nebula or the interstellar medium. The former is more likely since no other pulsars exhibit marked dispersion changes. Thus the plateau regions of D—from mid-May 1969 to mid-July 1969 and from June 1971 through August 1972—probably represent the base contribution of the nebula plus the interstellar medium The dilution of electrons in the nebula should appear as a negative slope in the plateau. Its absence allows us to place an upper limit on the Crab's contribution to D, provided that we can rule out any mechanism of increasing D that might cancel the dilution effect.

As a model, we assume that most of the contribution, D_{neb} arises from a thin spherical ionised shell of radius r and thickness Δ, rather than from a uniform sphere of electrons. We justify this on the basis of Shklovskii's observation[4] that the filaments, the highest-density regions, lie on the periphery of the nebula. (Trimble[2] has disputed this on the basis of radial velocity measurements.) Furthermore, radiation pressure will tend to sweep out the interior of a shell, at least in the beam of the pulsar.

The dispersion measure is defined as $D = \int n_e \, dl$, the electron number density integrated along the line of sight. Thus, if N electrons are uniformly distributed over the volume V of the shell

$$D_{\text{neb}} = \frac{N\Delta}{V} = N/(4\pi r^2) \tag{1}$$

Therefore the time derivative is

$$\dot{D}_{\text{neb}} = \frac{-N}{4\pi r^2} 2 \frac{\dot{r}}{r} = -2 \, D_{\text{neb}}/T \tag{2}$$

$T = r/\dot{r}$ is the 'kinetic age' of the nebula, 830 yr[2]. From the two plateaus in Fig. 1, we can place an upper limit of 5 s MHz^2 yr^{-1} on the decline of D (1 s MHz^2 = 7.43×10^{14} electrons cm^{-2} = 2.41×10^{-4} pc cm^{-3}), from which it follows that $D_{\text{neb}} < 2{,}100$ s MHz^2. This is slightly less than 1% of the total dispersion measure, 235,650 s MHz^2 (56.8 pc cm^{-3}). The result can be written as $\Delta = 0.5/n_e$ where Δ is measured in pc and n_e in cm^{-3}. For n_e comparable with filamentary densities (~10^3 cm^{-3}), the shell must be paper-thin compared with the nebula. It seems more likely that we observe the pulsar through a hole in the nebula, possibly cleaned out by the pulsar, where $n_e \sim 10$. It can now be seen that the assumption of a spherical shell was not crucial: a filled volume would require an even lower value of n_e to keep D_{neb} within the observed limit.

This determination of the Crab's fraction of the dispersion puts a contraint on the mass of ionised material it contains. For a spherical shell, the mass is

$$M = 4\pi r^2 n_e m_p (1+4f)\Delta \tag{3}$$

where m_p is the mass of the proton and f is the fractional abundance of He nuclei. Taking $f = 0.1$, $r = 1$ pc, and $n_e\Delta = D_{\text{neb}} \leq 0.5$ pc cm^{-3} gives $M = 0.21 M_{\odot}$. This must be

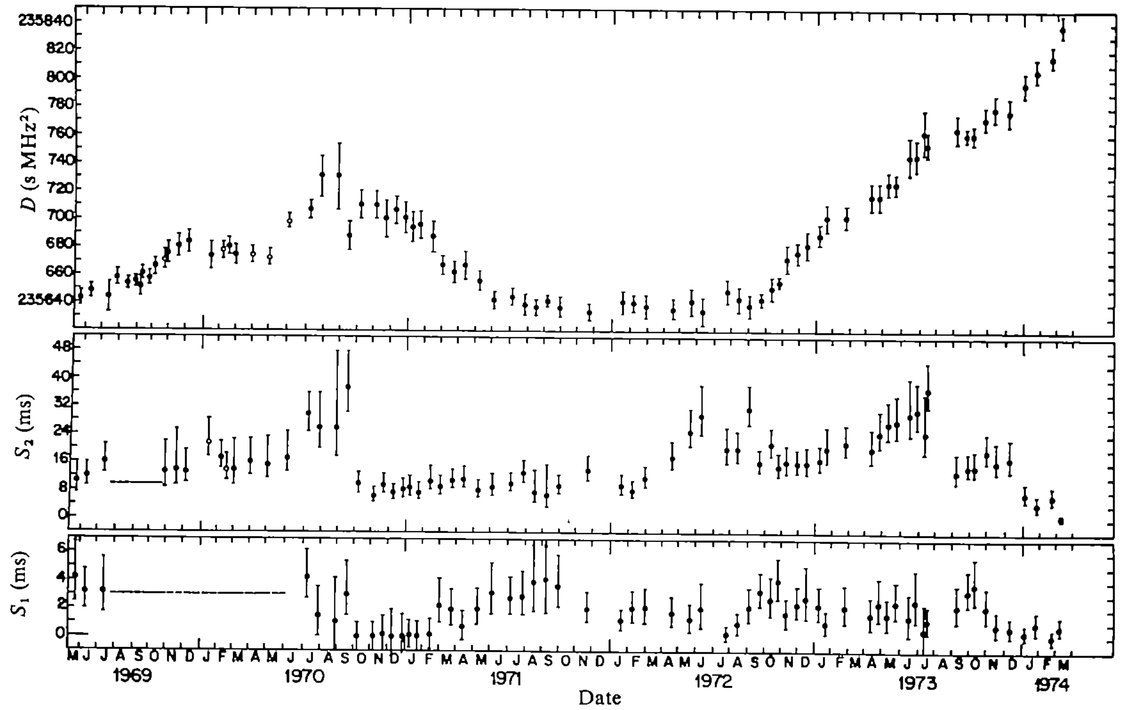

Fig. 1 Variability of the dispersion measure, D, of NP0532. (1 s MHz^2 = 7.43×10^{14} electrons cm^{-2}.) S_1 and S_2 are pulse-smearing time constants for a two-thin-screen multipath scattering model.

regarded as a lower limit, since looking through an abnormally sparse part of the nebula makes the total mass appear deceptively low. Trimble and Woltjer[5] derive $M \sim 1 M_{\odot}$ on dynamical grounds.

Since the contribution of the interstellar medium to the dispersion measure is higher than previously thought, the average electron density $\langle n_e \rangle$ in the line of sight (excluding the nebula) must be revised upwards. Davidson and Terzian derived $\langle n_e \rangle = 0.019$ cm^{-3} based on a 2-kpc distant nebula and $D_{\rm neb} = 1/3\ D$. Using a more accurate figure for the distance[2] (1.7 kpc) and $D_{\rm neb} = 0.01\ D$ gives $\langle n_e \rangle = 0.033$ cm^{-3}.

It is important that all of this holds true only if $\dot{D} = \dot{D}_{\rm neb}$, that any slope in the plateau of D in Fig. 1 is due entirely to nebular expansion. In principle, $D_{\rm neb}$ could be declining at the rate called for by Davidson and Terzian while being exactly compensated for by an increase in electron density elsewhere along the line of sight. In particular, those authors have pointed out that the Strömgren sphere engendered by ultraviolet and X-ray emission from the nebula has not had time to come to equilibrium. Integrating the Crab's spectrum[6] above the Lyman limit (by smoothly connecting the optical and X-ray spectra with a curve of spectral index 1.1) shows that the nebula puts out approximately as much ionising radiation as an 08 type star. If the density of atoms in the interstellar medium is $n_{\rm ism} = 0.15$ cm^{-3}, a Strömgren sphere of radius 70 pc will form in 5×10^5 yr. Since the nebula is less than 10^3 yr old, the ionisation front should be expanding, causing the dispersion measure of the pulsar to increase. Mitigating this effect is the extant Strömgren sphere of unknown size formed by the pre-supernova object. The contribution to D will change at the rate $\dot{D}_{\rm ss} = n_{\rm ism}\dot{R}$, where R is the velocity of the ionisation front. Provided $\dot{R} \ll 750$ km s^{-1}, we have $D_{\rm ss} \leqslant 0.5$ s MHz^2 yr^{-1}, which is insignificant. Since the expected ionisation front velocity a few tens of parsecs from the nebula is only a few hundred km s^{-1} (ref. 7), this will be the case. Hence this mechanism cannot compensate for the expansion of the nebula.

Another possible source of variation in D, which can, in principle, give rise to a systematic increase, is the 'wisps' near the pulsar, identified by Scargle[8]. These lie ~ 0.01 pc from the pulsar, and from their motions it seems that they are hydromagnetically coupled to it. However, their low surface brightness and the lack of Faraday depolarisation of the pulsar radiation implies that their density is probably very low. Since their characteristic size is ~ 0.01 pc, they contribute negligibly to the pulsar's dispersion measure.

Since the pulsar and the nebula are the only sources of ionising photons, any other mechanism for causing a secular increase in D must invoke the appropriate density fluctuations in the line of sight. The motions of these regions would have to compensate very precisely for the rate of dilution of electrons in the nebula, so their existance is improbable. We conclude that the dispersion plateau does indeed represent the base contribution of the Crab Nebula (in the line of sight to the pulsar) to the interstellar medium, from which it follows that (1) the nebula contributes less than 1% of the total dispersion measure of NP0532, (2) we are looking at the pulsar through a low-density hole in the nebula, (3) the mass of the nebula is at least $0.2 M_{\odot}$, and (4) the average electron density of the interstellar medium in the direction of the Crab is 0.033 cm^{-3}.

I thank Professors Yervant Terzian and John Rankin for several useful discussions on the subject. This work was supported by the National Astronomy and Ionosphere Center, which is operated by Cornell University under contract to the National Science Foundation.

The optical variability of 3C345

A SURVEY of the optical variability of compact extragalactic objects has been in progress at Asiago Observatory since 1967. Observations are taken mainly with the 67/92/215 cm Schmidt telescope on Eastman 103a-O emulsion plus a 2-mm GG 13 filter to match the B-system. A full account of the data obtained so far is now in preparation and will be published elsewhere, but it is worthwhile to report immediately on the variability of the quasar 3C345 because of its remarkable characteristics. Since Kinman *et al.*[1] discovered the large optical variations and the evidence of periodicities of 80 and 320 d, several papers have appeared reporting photometric observations of this object, whose behaviour is, therefore, unusually well covered. Also, 3C345 displays an apparent 'super-light' expansion at radio frequencies (see Cohen *et al.*[2]).

We have collected in Fig. 1, 485 B-magnitudes by Kinman *et al.*[1], Barbieri and Erculiani[3], Tritton and Selmes[4], Smyth and Wolstencroft[5], McGimsey *et al.*[6], Selmes *et al.*[7], Markova *et al.*[8], *Markova and Zhukov*[9] and from unpublished data obtained at Asiago. To simplify discussion, observations in other photometric systems (such as P-magnitudes) have been discarded and values obtained on the same day have been averaged together, so that the minimum time interval between two points in Fig. 1 is one day. The timespan covered by the data is 3,965 d. Three strong brightenings can be recognised during this period, when the object reached magnitudes brighter than the 16th. In the first and third occasion (1967 and 1971 respectively), the behaviour was very complex, with oscillations larger than 0.5 mag taking place in less than 10 d; on the second occasion (mid-1969) there was a single burst of short duration not accompanied by the slow increase seen before and after. To analyse this light curve in a quantitative way, we have employed a procedure suggested by Deeming[10] for the Fourier analysis of unequally spaced data.

A fuller discussion of our data are given elsewhere[11]; here only an important result is reported. The power spectrum PN shows three peaks, a narrow one at $\nu = 0.00065$ (period 1,540 d), a broader one at $\nu = 0.00125$ (period 800 d), and finally a smaller peak at 140 d. The region around 80 d shows an irregular structure with no definite feature, and actually the disappearance of this periodicity after a few cycles has already been discussed by Kinman[12]. The precise value of the largest period is not well determined by the timespan of the data in Fig. 1, 3,965 d, and, therefore, periods ranging from 1,420 to 1,650 d can be considered equally possible. One of them, however, is *a priori* especially attractive, that at 1,600 days, not only because it is a multiple of 800 but also because its difference of phase with the component at 800 d is almost exactly $\pi/2$ (the phases are computed from the imaginary and real parts of the Fourier transform). We have therefore attempted to synthesise the data of Fig. 1 with these three harmonics. Regarding their amplitudes, in the present situation the total lack of data when the object is close to the Sun and the scanty information available on other occasions will appreciably reduce PN at periods lower than one year. After trials, the amplitude of the component at 140 d has been increased to 0.25 mag from its computed value of 0.14 mag. The other two harmonics have amplitudes equal to $(2PN)^{1/2}$.

The solution is then

$$\begin{aligned} f(t) = {} & 16.61 + 0.35 \cos(2\pi t/1600 + 0.85) \\ & + 0.32 \cos(2\pi t/800 - 0.72) + 0.25 \cos(2\pi t/140 + 0.46) \end{aligned}$$

which is shown in Fig. 1 as the solid line. This solution, reproduces with fair accuracy the mentioned complex maxima and single burst, although it is clearly impossible to have a precise

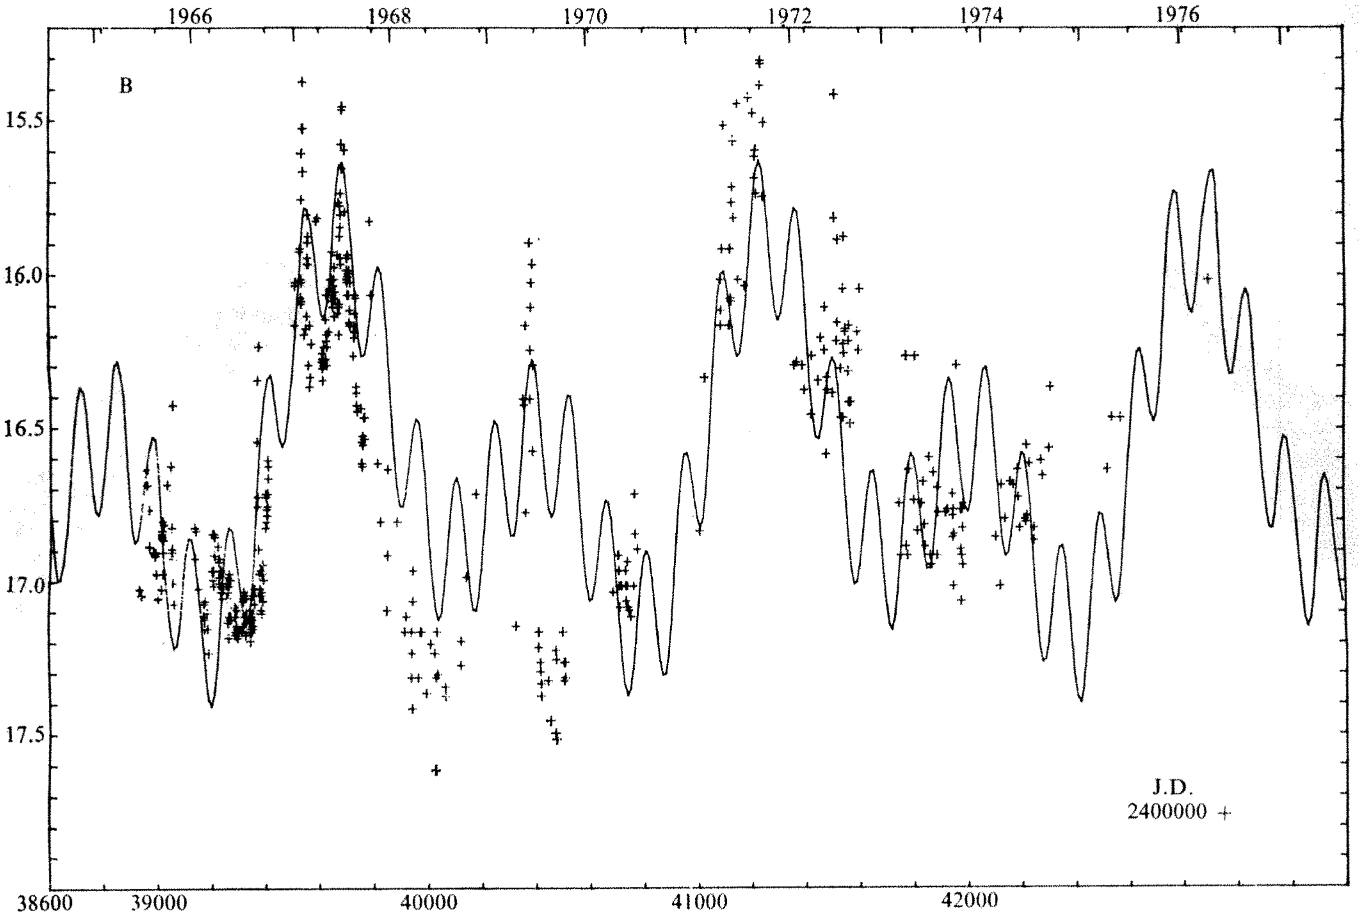

Fig. 1 The light curve of 3C345 from 1965 to 1976. +, B magnitudes taken from the literature quoted in the text. —, Harmonic solution $f(t)$ derived from our analysis.

representation of this latter feature with low-frequency components.

Other solutions with periods slightly different from 1,600 and 800 d have been explored and obviously give a rather similar representation. The best periods can be obtained only by a long extension of the data in the future or in the past. Historical data on the light curve of 3C345 have been published by Angione[13] and cover the years from 1896 to 1953. If the solution of Fig. 1 is extended over these past observations, a good agreement is found although, unfortunately, the points are too few to be conclusive evidence. Observations in the years to come will be necessary to prove beyond doubt the presence of periodic phenomena in 3C345.

Small-amplitude, short-period waves in the E and F regions of the ionosphere

ACCURATE measurements of the virtual height of radio waves reflected from the ionosphere have been made by using a phase path ionosonde[1]. This instrument determines the virtual height, h', from the variation of echo phase with frequency, $\varphi(f)$, since $h' = (c/4\pi)(\partial\varphi/\partial f)$. Measurements are made in two ways. First, the ionosonde is swept in frequency and h' determined by taking the Fourier transform of the phase measurements on a number of frequencies. This is a form of pulse synthesis and very narrow pulses may be synthesised by combining measurements over a relatively wide frequency range[1]. The second mode of operation is to repeatedly step the ionosonde through 20 frequencies in 0.4 s so that detailed time variations and height structure can be measured. Provided there are no overlapping echoes, virtual heights can be calculated by determing $\partial\varphi/\partial f$ from adjacent frequencies. Suitable choices of frequency intervals can give very accurate values of h' (ref. 2). This paper presents results which show that small-amplitude (< 500 m peak to peak), short-period (~ 10 s) waves can occur in the E and F regions of the ionosphere.

Figure 1*a* shows an ionogram obtained by the phase path ionosonde using the pulse synthesis technique. A blanketing sporadic E layer is apparent and apart from effects due to interference at 2.5 MHz and 3.5 MHz, the virtual height is constant within 293 m over the frequency range 2–7 MHz. The value of 293 m corresponds to the quantisation level, of the pulse synthesis technique, used on this occasion. After recording this ionogram, the ionosonde was stepped from 2.0–3.9 MHz in 100-kHz steps. The variation of group path with time for several frequencies are shown in Fig. 2*a*. All frequencies show that in the 3 min for which data is presented, there is an overall

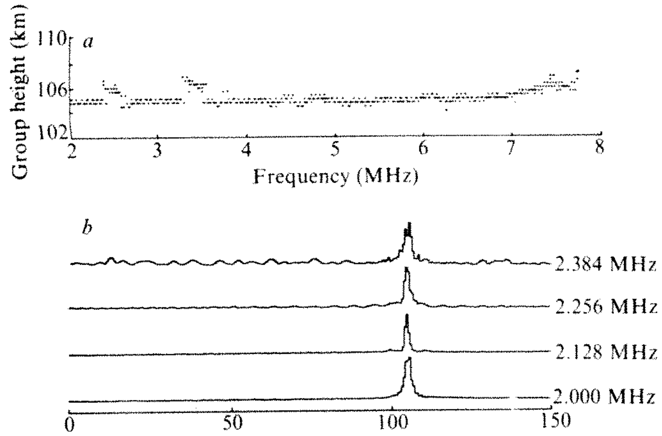

Fig. 1 *a*, An accurate ionogram produced by the phase path ionosonde using a pulse synthesis technique; *b*, examples of synthesised echoes.

rise and fall in the sporadic E layer. Superimposed on this, the three lowest frequencies show two bursts of oscillations. For the first, the period is about 11 s and the peak to peak amplitude is 240 m in virtual height. For the second burst, the period is 6.9 s and the peak-to-peak amplitude is 180 m. The oscillations are phase shifted in time on each of the frequencies and the period also varies slightly with the radio frequency. On 2.5 MHz the oscillations have decreased considerably in amplitude. Even though there is interference at 2.5 MHz, the group height can still be found since it is determined by calculating $\partial\varphi/\partial f$ using frequencies on either side of 2.5 MHz. On 3.4 MHz the first burst of oscillation is not apparent and although oscillations occur at about the time of the second burst on the lower frequencies, the period and amplitude are different. Figure 2*b* shows similar data beginning 2 min later and lasting for 180 s. During this time the behaviour is in marked contrast to that shown in Fig. 2*a*. The sporadic E layer remained at an almost constant height and although there are small variations, there are no pronounced oscillations of approximately constant period.

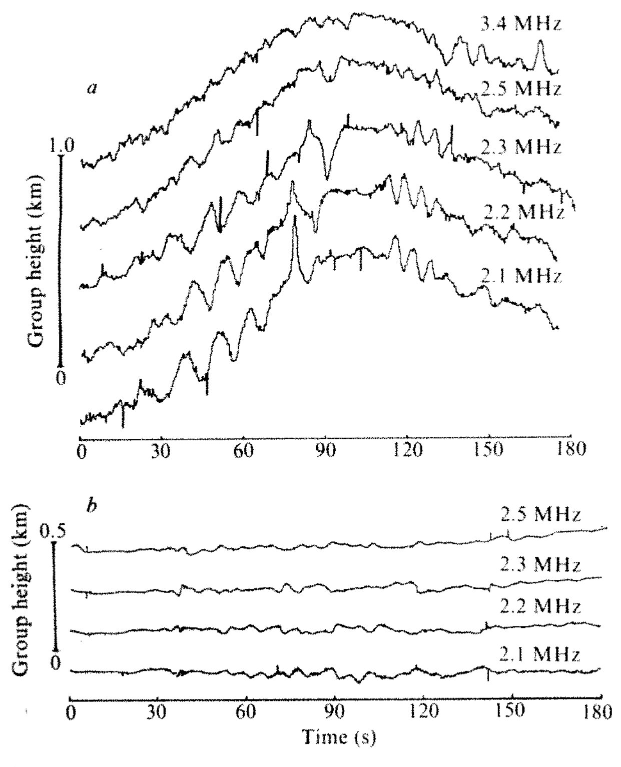

Fig. 2 *a*, The variation of group height with time on several frequencies reflected from sporadic E; *b*, similar data to *a* but beginning 2 min later.

We are confident that the bursts of oscillation represent real effects associated with the sporadic E layer. Firstly, there is strong evidence that at an instant only one reflection point is involved. The reasons for this are that the sporadic E layer has such a constant virtual height over a wide frequency range and the synthesised echoes obtained for the ionogram in Fig. 1*a* do not show pulse spreading (see Fig. 1*b*). Secondly, if they were an artefact of the instrument (such as beating with the mains supply), the oscillations would appear on all frequencies and the time variations would be in phase and have the same period. The third point to be considered is that the antenna system used was not polarised so that there is no discrimination between ordinary and extraordinary propagation modes. The constant virtual height against frequency of the sporadic E layer indicates that there is relatively little ionisation below this layer, so that the virtual range of ordinary and extraordinary rays will differ only marginally. Since the extraordinary mode is strongly absorbed, our observations basically refer to the ordinary mode. However, one question to be answered is whether the variations shown in Fig. 2*a* could be caused by differential absorption effects. If such effects are due to time variations in the D layer, and, therefore, well below the reflection level, the time variations on the different frequencies should be in phase. If such effects occur near the reflection level then it means that the small-period oscillations are in fact occuring in the sporadic E layer.

The period of the oscillations is too short to be gravity waves but they could be sound waves. However, the fact that the oscillations occur only on a few frequencies suggests that they may be confined to a small part of the sporadic E layer and since they occur for only a short time, we may be observing bursts of irregularities produced by plasma instabilities occurring in the sporadic E layer. The amplitude of the oscillations is small but cannot be directly interpreted as the changes which are occurring in the real height of the reflection point because virtual height changes can be an overestimate of the true height changes and angle of arrival effects can occur as well.

Oscillations of short period (~ 4 s) and small amplitude (~ 250 m peak to peak) have also been observed in the F region but they are not so confined in height. Again they may well be the effects of either sound waves or plasma instabilities. Such short-period small-amplitude phenomena do not seem to have been detected in the ionosphere before and they are being studied further in order to explain them in detail.

Radioactive ^{38}S in an atmospheric SO_2 and SO_2 oxidation rate measurement

BHANDARI *et al.*[1] and independently Perkins *et al.*[2] have detected cosmic-ray-produced ^{38}S in several precipitation samples. This paper reports on the first detection of cosmic-ray-produced radioactive ^{38}S as atmospheric $^{38}SO_2$. The use of this nuclide as a tracer for the *in situ* determination of SO_2 oxidation rates is also discussed. ^{38}S is produced by spallation of atmospheric argon and decays with a half life of 2.87 h by β^--emission to ^{38}Cl; 95% of the decays are accompanied by 1.88 MeV-γ-radiation, 5% undergo direct transition to the ^{38}Cl ground state.

The present work on the *in situ* measurement of SO_2 oxidation rates within the complex system of the natural atmosphere (where no other direct method to determine SO_2 conversion rates is known) began because we felt this could be a very interesting application of cosmic-ray-produced sulphur.

The radioactive sulphur, which after the spallation is present as sulphur dioxide, participates in the chemical fate of environmental SO_2 and is oxidised and converted to sulphate in the same manner and $^{38}SO_4{}^{2-}$ also decays. The ratio of radioactive SO_2 to radioactive $SO_4{}^{2-}$ depends on the ratio of the radioactive decay rate to the SO_2 conversion rate. Thus simultaneous measurements of ^{38}S-radioactivity in SO_2 and in particulate, $SO_4{}^{2-}$ should give information on the SO_2 conversion rates.

For sampling SO_2, atmospheric air is sucked, with a flow rate of about 150 $m^3\ h^{-1}$, through a paper filter (Macherey, Nagel & Co. MN 714) for removal of particulate matter and then through an absorption chamber. In this absorption chamber, a solution of 0.1 M NaOH and 1.5% H_2O_2 is sprayed into the air stream. More than 97% of SO_2 is absorbed by the dispersed solution. Within this solution SO_2 is oxidised and is precipitated as $BaSO_4$. Sulphate is reduced to H_2S by a procedure similar to that described by Polson and Strickland[3], and by Stoeppler[4]. H_2S is directly used as counting gas in an internal-gas β-radiation detector. Details of the sampling procedure as well as of internal-gas counting will be published elsewhere.

In order to reduce detector background, and to discriminate against ^{35}S (half life 87 d; no γ-radiation) which is also present in atmospheric samples, low-level β-γ-coincidence technique as described by Roedel[5] is used. The internal-gas counter tube of ~26 cm^3 volume is fitted in the well of a 5 × 5-inch-NaJ(Tl)-scintillation crystal. The scintillation crystal registers the γ radiation and is gated by the β radiation detected in the gas counter. For the 1.88-MeV γ peak there is a detection efficiency of $7\pm0.8\%$ and a background counting rate less than 10^{-3} events min^{-1}.

Five samples have been measured between 5 February and 3 March 1976. The activities varied between 1 and 2×10^{-3} d.p.m. $^{38}S\ m^{-3}$, the mean being 1.3×10^{-3} d.p.m. m^{-3} (d.p.m. is disintegrations per minute). Sample volumes varied between 325 m^3 and 520 m^3. Due to the very poor counting statistics the uncertainties are still very great (about $\pm0.7\times10^{-3}$ d.p.m. m^{-3}).

Unfortunately, it is not yet possible to measure ^{38}S as airborne particulate $^{38}SO_4{}^{2-}$. As mentioned above a filter is used to retain and collect aerosols. This filter, however, causes also an appreciable retention of SO_2. This effect is most probably due to catalytic oxidation of SO_2 to $SO_4{}^{2-}$, induced, for the most part, by the collected aerosols. The loss of SO_2 amounts to ~10% in new unloaded filters and to ~30–50% in filters loaded with aerosols. This indicates that ^{38}S-activity found on the filters is, for the greater part, due to a contamination by SO_2 converted within the filters. An improved sampling technique, however, is being developed which, together with an increased efficiency of radiation detectors, should allow simultaneous measurements of $^{38}SO_2$ and $^{38}SO_4{}^{2-}$.

Finally, we shall give a rough estimation of the limits of the radiosulphur method. For this estimate only first-order reactions for the SO_2 conversion are allowed, further ^{38}S is assumed to be primarily present as SO_2 (this has still to be investigated), and transport and removal processes are ignored. Then the following equation for the $^{38}SO_2/^{38}SO_4{}^{2-}$ balance holds

$$d[^{38}SO_4{}^{2-}]/dt = +k[^{38}SO_2]-\lambda[^{38}SO_4{}^{2-}] \qquad (1)$$

(λ and *k* are the constants of radioactive decay and of conversion, respectively).

In a steady state, equation (1) reduces to

$$k = \lambda[^{38}SO_4{}^{2-}]/[^{38}SO_2] \qquad (2)$$

If a ratio $[^{38}SO_4{}^{2-}]/[^{38}SO_2]$ in the order of 0.1 can be detected, the minimum conversion rate which can be determined, is $k = 0.1\ \lambda$ (with $\lambda = 0.242\ h^{-1}$) or about 2.5% h^{-1}. Laboratory experiments suggest that reaction rates for homogeneous SO_2 oxidation in urban air lie between 0 and 10% h^{-1} (Cox and Penkett[6], Cox[7]). Haury and Jordan[8,9] report reaction rates for heterogeneous oxidation on the surface of aerosol particles up to 15% h^{-1} depending on the relative humidity (Haury's and Jordan's measurements, however, are made at very high concentrations of SO_2 and aerosols).

The expression for *k* given above does not depend on the ^{38}S production rate. Nevertheless, the specific activity of $^{38}SO_2$ may be affected by the vertical variance of the production rate. In the lower atmosphere, the spallation rate increases by a factor of ~2 with every 1.5 km up[10,11], a part of this elevated activity may be mixed downwards by eddy diffusion. The maximum additional increase of the $^{38}SO_2$ concentration can be estimated by Fick's equation for the turbulent mixing

$$\frac{1}{[^{38}SO_2]}\ \frac{\partial[^{38}SO_2]}{\partial t}\bigg|_{mix} = \frac{1}{[^{38}SO_2]}\ \frac{\partial}{\partial z}\left(K_z\ \frac{\partial[^{38}SO_2]}{\partial z}\right).$$

$$\approx \frac{1}{[^{38}SO_2]_{z=0}}\ K_z\ \frac{[^{38}SO_2]_{z=z_0}}{z_0{}^2} \approx 2K_z/z_0{}^2 \approx 6.5\%\ h^{-1} \qquad (3)$$

(K_z being the coefficient of vertical eddy diffusion, which is assumed to be $2\times10^5\ cm^2\ s^{-1}$, and $z_0 = 1.5$ km being the scale height for doubling the production rate, *z* is the vertical axis) or an increase of the $^{38}SO_2/^{38}SO_4{}^{2-}$-ratio of 20–25% within the lifetime of ^{38}S. This estimate, however, gives an upper limit for the error in the $^{38}SO_2/^{38}SO_4{}^{2-}$ ratio. In most cases one may assume an averaging within the scale of $\sigma_z = \surd(2K_Z/\lambda) \approx 750$ m rather than an appreciable increase of the $^{38}SO_2/^{38}SO_4{}^{2-}$ ratio.

Furthermore, the SO_2 to $SO_4{}^{2-}$ balance in the real atmosphere may be affected by horizontal ventilation and by the uptake of SO_2 by plants and soils (see, for example, ref. 12 and references quoted therein).

Stresses at spherulite boundaries

IN a recent study of drawing behaviour in polyethylene Barham and Keller[1] discussed the black lines which are often seen around spherulites of polyethylene viewed between crossed-polarisers. They state that these dark lines seem to be independent of their orientation with respect to the polarisation directions and attribute them to poorly crystalline regions of low molecular weight material. Here I offer an explanation for these lines and show that they reveal the presence of stresses at the spherulite boundaries.

Figure 1 shows a 5-μm thick film of polyethylene ($\overline{M}_n = 11{,}100$, $\overline{M}_w = 68{,}000$) prepared by dropping a *p*-xylene solution on to a hot microscope slide, drying and melting the polymer and rapidly cooling. The dark lines surrounding the banded spherulites can be seen. Note that boundaries are not dark if they make an angle of between about 30°–60° to the polarisation directions parallel to either edge of the figure. Rotation of the sample causes the dark bands to become as light as the rest of the spherulite, when the boundary is inclined at about 45° to the polarisation directions.

This suggests that the boundaries contain oriented polymer; but similar dark lines can be seen at boundaries between small, suitably oriented non-polymeric crystals. One explanation is that the dark band arises when light crosses the boundary during its passage through the specimen. The equations for polarised light passing through two superimposed crystal plates[2] show that extinction can occur when the slow and fast optical axes have a mirror symmetry across the boundary and the boundary is parallel to one of the polarisers. If the optical axes make an angle of 45° with the boundary the intensity I is given by $I = \sin^2[(\delta_1 - \delta_2)/2]$ where δ_1 and δ_2 are the two retardations. Thus, extinction will occur if the retardations are equal. If the angle of the optical axes to the boundary varies from 45° the system will still be close to extinction. If the boundary is tilted an arbitrarily small amount with respect to the light path, slightly different light paths will cross different thicknesses of the two crystal plates, and there will be one path where extinction occurs. The argument is more involved for banded spherulites such as polyethylene, but the result is still that an extinction line should be seen at the boundary and there is no reason to postulate the presence of a boundary film to explain the black line.

Further information can be derived by considering the regions of the spherulite where the boundary line zig-zags as can be seen in Fig. 1. Corresponding zig-zags can also be seen by using light Nomarski interference microscopy and scanning electron microscopy (SEM) though these lack the clarity and contrast of the polarised light views. Three origins for these zig-zags seem possible. The first is that the boundary may be tilted so much that the extinction position wanders from side to side. This idea is eliminated by observing these uneven boundaries by SEM and reflected light, and by the lack of any significant change as the sample is tilted during polarised light observation. The second possibility is that the two spherulites interpenetrate to produce a zone of changing birefringence. The observation of similar black lines between suitably oriented crystals of simple compounds shows that interpenetration is not necessary. The SEM and reflectance microscopy confirm the third possibility, that the zig-zags are real.

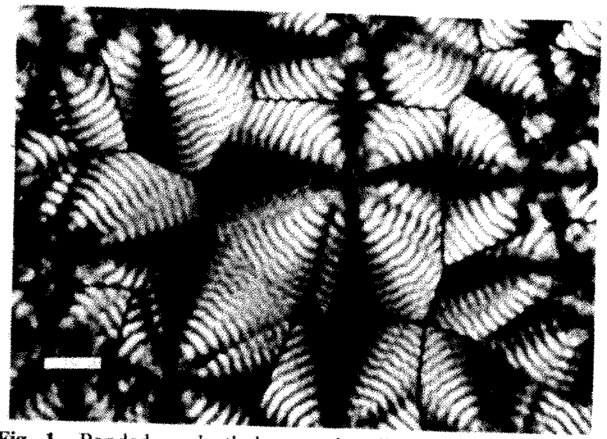

Fig. 1 Banded polyethylene spherulites showing zig-zag boundaries. Scale bar 10 μm.

These zig-zags occur where the band structures in the two spherulites intersect at an angle of about 90° and also where the banding is so out of phase that a dark band in one spherulite is crystallising adjacent to a light band in the other spherulite. In these circumstances the light band always protrudes into the dark one. Thus the light band, where the chains within the crystals are in the plane of the film and perpendicular to the spherulite radius[3], grows faster than the dark band, where the chains are perpendicular to both the plane of the film and the spherulite radius. Since the crystal twisting frequency in angle per unit length is unchanged, the net result is that each spherulite alternately cuts across the front of the other then slows down as the lamellar crystals twist into the dark orientation. This is illustrated in Fig. 2. This effect is not restricted to thin films; the same zig-zag boundaries with the same light–dark relationship are observed in some regions of microtomed slices of bulk samples.

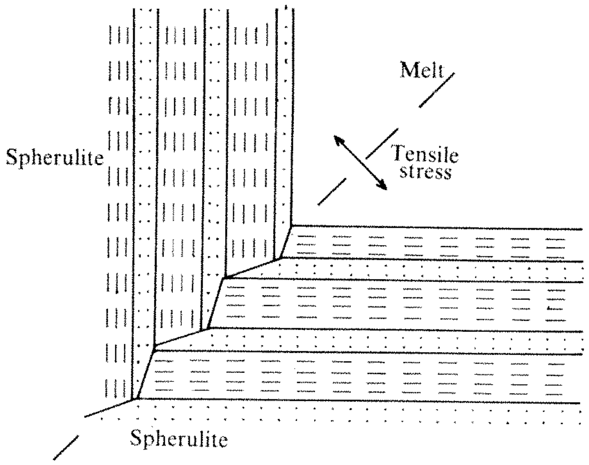

Fig. 2 Structure at a zig-zag boundary. Lined bands: bright, chains parallel to lines. Dotted bands: dark, chains perpendicular to paper.

In a bulk sample, when a microtomed section contains the centres of two spherulites and their common boundary, the plane of the boundary must be perpendicular to that of the section. The dark bands will then always contain crystals aligned with the chains parallel to the boundary and perpendicular to the section, while the chains in the bright bands are at an angle to the boundary.

The 10% shrinkage that occurs as spherulites form will produce a radial tensile stress and tangential compressive stress in the melt which will decay at a rate characterised by the melt relaxation time[4]. Where spherulites approach, the liquid layer trapped between the two may be unable to relax and a tensile stress perpendicular to the common boundary will develop.

The case where zig-zags form is shown in Fig. 2. Here the spherulite radii are both at 45° to the boundary and the banding is out of step. From studies on cross-linked polymers it is known that tensile stress increases the growth rate of crystals where the chain axis is parallel to the stress axis[5]. In Fig. 2 the tensile stress will have a component parallel to the chain axis in the light band but not in the dark band, so that the growth rate of the light band will be increased.

From the angle of the zig-zag we can make an order of magnitude estimate of the boundary stress. Taking the angle between the zig and zag to be about 60° we obtain a growth rate ratio of 1 : 1.5. Putting this into a thermodynamic theory of polymer crystal growth under stress[6], taking the undercooling as 30 °C and assuming that the stress does not affect the growth rate transverse to the stress we obtain a local strain of about 0.3 or a stress of about 6×10^5 N m^{-2} (6×10^6 dyn cm^{-2}). This can be taken as an average strain over a zone corresponding to the span of the zig-zag.

Black boundary lines having similar properties have been seen in several spherulitic polymers formed as thin films on glass slides. In some cases non-birefringent dark lines were also seen. Barham and Keller have shown that the extent to which these lines can be seen depends on the molecular weight distribution and crystallisation conditions. Polyoxymethylene and poly(ethylene adipate) form banded spherulites where the boundaries are often irregular but do not show clear zig-zags. Residual boundary stresses of this magnitude must affect the strength and oxidation and corrosion resistance of polymers.

I thank A. Keller and P. J. Barham for their helpful comments.

Transport of metal complex chlorides through plastic film membrane

THE acid–metal–chloro complexes of gallium and iron have been shown to be transported through polyurethane membranes by virtue of an acid or chloride gradient. Vofsi and co-workers[1–3] have reported on transport of uranium using complexing plasticisers in thin plastic films. More recently, the transport of sodium across a liquid membrane was described[4]. Recent work[5] has demonstrated that open cell polyurethane foam sponge with surface areas of less than 0.1 m^2 g^{-1} can dissolve gallium or iron as the HMCl$_4$ complex to as much as 10% of the foam by weight. In this note, we investigate the transport of metal complexes, such as HMX$_4$ of gallium and iron, across polyurethane plastic films. We believe that the acid-chloro complex could dissolve in the film and so pass through such membranes.

Our all-glass diffusion apparatus consisted of two equal volume flanged cells with top openings for sampling. The 125-μm polyurethane film (ether type) was sealed vertically between the two glass flanges with high vacuum Silicone or Kel-F grease and clamped. Platinum electrodes sealed in glass were used to determine the specific conductance of the water (receiver) side which indicated the extent of migration of gallium from the loaded cell. The apparatus was immersed in a constant temperature bath controlled at 20±1 °C and the solutions were stirred with magnetic stirrer and Teflon-coated magnets. Small (1 or 2 ml) samples were periodically removed from the receiver side (Fig. 1) or both sides (Fig. 2) of the diffusion apparatus and analysed for acid and metal. Gallium was determined by AAS (ref. 6), whereas iron and uranium were analysed spectrophotometrically by the thiocyanate complex.

The effect of acid strength and chloride concentration on the extent of diffusion of gallium through the polyurethane membrane is shown in Fig. 1. The results for the diffusion of 200 p.p.m. gallium from 3.10 M HCl is not shown but after 500 h gave less than 1 p.p.m. gallium in the water cell which had a specific conductance of 0.17×10^{-3} Ω^{-1} cm^{-1}. The rate of diffusion of gallium is qualitatively similar to the solvent extraction efficiency of the polyurethane foam[5,7], and is believed to be due to the equilibria

$$\mathrm{H^+ + Ga^{3+} + 4\,Cl^- \rightleftharpoons HGaCl_4(aq)} \qquad (1)$$

$$\mathrm{HGaCl_4(aq) \rightleftharpoons HGaCl_4(foam)} \qquad (2)$$

The depletion of gallium from the loaded cells was determined analytically and Ga was found to have decreased from 200 p.p.m. initially to less than 1 p.p.m. at the conclusion of the experiments. The final concentration of gallium in the receiver cell was, in some cases, greater than the initial 200 p.p.m. (the membrane initially separated equal volumes of solution) because of an osmotic effect which was noticed when most of the gallium had diffused through the membrane. The osmotic effect depleted water from the water cell causing the volume of the loaded cell to increase. The volume of water transported was about 10–20% of the total volume. This was primarily accommodated by the bulging of the membrane into the water cell.

The mechanism of transport is readily explained by equations (1) and (2). The HGaCl$_4$ complex is formed in the acid (loaded) cell dissolves in the membrane through which it can diffuse. As the complex appears on the water (receiver) side it dissociates back to the component ions, H$^+$, Ga^{3+} and Cl$^-$. The Ga^{3+} ion cannot diffuse back until the concentration of the HCl has increased significantly to reform the HGaCl$_4$ complex. This back diffusion has been observed with iron (III) where it was also noted that the initial hydrolysis of the HFeCl$_4$ complex in

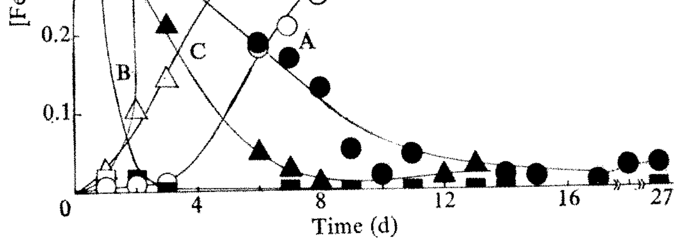

Fig. 2 Diffusion of iron from loaded cell (solid symbols) through polyurethane membranes into receiver cell (open symbols) as a function of time. *a*, Circles: 620 ml of 0.4 mg ml^{-1} Fe^{3+}, 2 M HCl, 5 M LiCl with 620 ml of 2 M HCl in receiver cell, membrane area 42 cm^2. *b*, Squares: 300 ml of 0.4 mg ml^{-1} Fe^{3+}, 2 M HCl, 5 M LiCl with 300 ml of 0.1 M HCl in receiver cell, membrane area 21 cm^2. *c*, Triangles: 750 ml of 0.4 mg ml^{-1} Fe^{3+}, 2 M HCl, 5 M LiCl, with 750 ml of 2 M HCl in receiver cell, membrane area 50 cm^2. Cell preconditioned with HCl and LiCl for 6 d before Fe^{3+} was added.

water precipitated the red-brown $Fe(OH)_3$ which was deposited on the water side of the membrane. The precipitate then dissolved slowly as the acid diffused through the membrane. This may have occurred for gallium but was not noticed because the $Ga(OH)_3$ is not coloured. The formation of the $Fe(OH)_3$ indicates that the acid–metal complex diffuses through the membrane faster than HCl.

When a low-acid (3 M HCl) gallium system was studied with added LiCl (3 M) the diffusion rate was much faster than for 3 M HCl but not as fast as for 6 M HCl. This is consistent with the formation of the complex and its solubility in polyurethane[5]. On completion of the experiment (230 h) (Fig. 1 *b*), analysis for lithium by AAS in the water cell showed that less than 1 p.p.m. may have diffused through the membrane.

The results for the diffusion of iron (III) through the membrane are shown in Fig. 2, where the receiver cell contained 2 M and 0.1 M HCl to prevent the hydrolysis of the iron complex to insoluble hydroxide. The rate of diffusion of the iron is greatly affected by the strength of the acid in the receiver cell. The time lag noted for the appearance of metal in the receiver cell was significantly reduced when the membrane was conditioned for six days in the cell with acid and LiCl before the iron was added (Fig. 2 *c*). This implies that the mechanism of transport of the metal is primarily via the anion complex, MCl_4^-, which jumps from one protonated ether group to another. The membrane morphology had changed considerably during the diffusion experiments and the appearance of blisters, vacuoles, resemble the changes observed by Vofsi[8] with plasticised membranes.

The diffusion of iron (III) chloride in 6 M HCl solution was tested with membranes of 50 μm polyethylene, 25 μm Saran, 25 μm PVC and 50 μm Teflon. In all these cases no detectable iron had diffused through the membrane in 15 days. Iron (II) chloride in 6 M HCl did not diffuse through the polyurethane membrane whereas iron (III) bromide in HBr solution was slightly slower than the iron (III) chloride. Preliminary experiments with $UO_2(NO_3)_2$ in the presence of $Al(NO_3)_3$ showed diffusion of uranium to be occurring through polyurethane membrane.

Long-period effects in the Romanian earthquake of March 1977

THE field study of the Romanian earthquake of 1977 suggests that strong ground motions, for engineering purposes, may differ considerably from those currently adopted for design on the basis of US West Coast-type of recordings. The earthquake of March 4 1977 in Romania had a magnitude of $M = 7.2$ and a depth of about 90 km. It originated from the source of intermediate-depth earthquakes of Vrancea, beneath the bend of the Carpathian mountain arc, at 45.8°N, 26.7°E, a source similar to that of intermediate events in the Hindu Kush.

It was felt over an area of 1.3×10^6 km^2 and caused damage over an area of about 80,000 km^2 within which the most frequently occurring intensity did not exceed VII (MM). It mostly affected the densely populated and rapidly developing centres of Craiova, Pitesti, Zimnicea, Bucharest, Ploesti, Focsani, Birlan and Iasi, where it caused damage worth over 10^9 $ US. The earthquake killed about 2,100 people of whom 1,800 perished in Bucharest (BU), and injured 10,500, 2,300 seriously. Much of the damage was caused to old multi-storey reinforced concrete buildings of 6–12 storeys. Some of them had been damaged in 1940 by an earthquake of almost identical characteristics and by the war. Relatively few modern high-rise constructions suffered serious structural damage.

In Bucharest, at a focal distance of 190 km, the shock triggered an SMAC-B strong-motion accelerograph and a Wilmot seismoscope in the basement of a single-storey structure founded on thick, compact alluvium. The SMAC record shows that the strongest shaking began about 19 s after the instrument started to record, and this strongest shaking consisted of a double acceleration pulse in the two horizontal components of 154 and 206 gal respectively that contain more than 80% of the total energy flux of the event. Figure 1 shows the acceleration response spectrum (S_a), for 5% critical damping, of the main portion of the north–south component of motion[1]. It also shows the response spectra of two other ground motions produced by earthquakes of roughly the same magnitude, in the near-field (El Centro, EC) and in the far-field (Mexico City, MX) for comparison. The former occurred on 19 May 1940 at a depth of about 7 km, had a magnitude $M = 7.1$ and was recorded on dense alluvium at a focal distance of 14 km. The latter occurred on the 11 May 1962 at a depth of about 40 km, had a magnitude $M = 7.0$ and was recorded on very soft and thick deposits of high water content at Mexico City, at a focal distance of 270 km. The difference in shape of the response spectra between far-field (BU and MX) and near-field (EC) as well as the shift of the spectral maxima is obvious. This difference is more apparent in Fig. 2 where the response spectra of Fig. 1 have been normalised with respect to their corresponding zero period accelerations. Allowing for the larger magnification in the MX record for periods longer than 2 s, due to layer

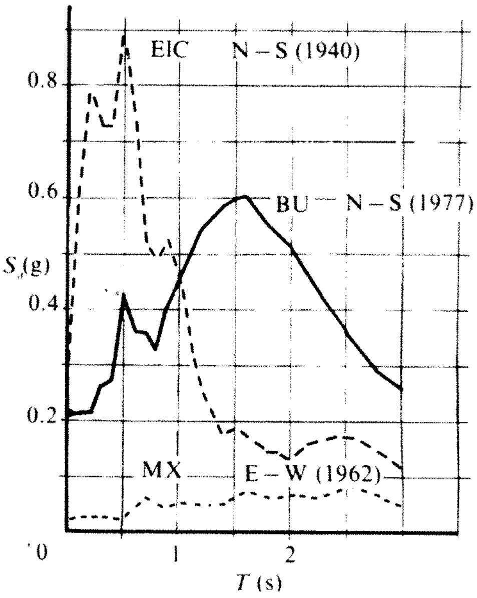

Fig. 1 Acceleration response spectrum of the main portion of the north–south component of motion in the Bucharest earthquake. The ground motions produced by other earthquakes in El Centro and Mexico City are shown for comparison.

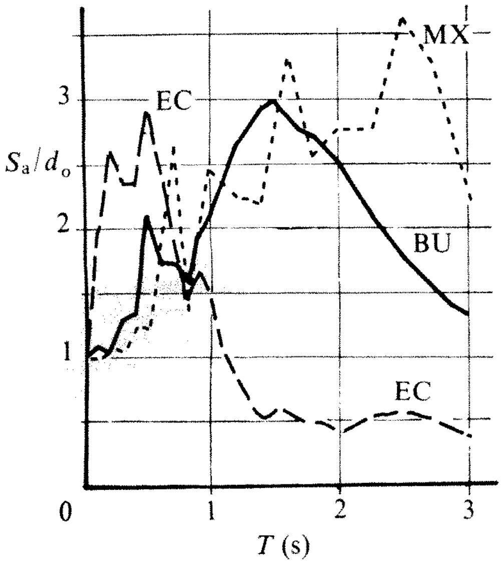

Fig. 2 Normalised spectra from Fig. 1 with respect to their corresponding zero period accelerations.

response, all three events show the same maximum amplification of about three times their zero period acceleration but at distinctly different periods, much longer for the far-field motions.

There is, of course, insufficient evidence to claim that the (BU) spectra are representative of an intermediate depth, medium magnitude earthquake. They simply imply that in this particular case the focal mechanism and preferential attenuation at higher frequencies along the path produced intense ground motions at unusually high periods.

These long-period characteristics of intermediate-depth earthquakes from the Vrancea region are reflected also on the seismoscope recordings. In Bucharest, the recording of the Wilmot seismoscope shows a double amplitude of 41 mm which is consistent with 44-mm amplitude response of the SMAC-B record at $T = 0.75$ s and 10% damping. At Galati, at a focal distance of 140 km the double amplitude was 27 mm; at Nis and Skopje in Jugoslavia, at distances of 480 and 610 km, the Wilmot amplitudes were about 6 and < 1 mm respectively. Other earthquakes originating from Vrancea, those of 2, 15 October and 14 December 1966 of magnitude 5.6, 5.4 and 5.2 produced seismoscope amplitudes at Ksihinev in the USSR, at a focal distance of 260 km, of 1.7, 1.4 and 0.7 mm respectively.

The greater effect of the 1977 earthquake in Bucharest was on flexible, 6–12-storey high reinforced concrete frame structures of low ductility without shear walls. These structures have a fundamental period of the order of 0.7–1.6 s, which places them on the ascending branch of the BU spectrum. Progressive damage during the earthquake should have caused a lengthening of their period and an increase in the lateral forces acting on them, whereas for the EC spectrum just the opposite is true. In contrast, rigid structures of large panel or frame construction with shear walls, of the same height, as well as 1–3-storey masonry dwellings, suffered little damage. These structures have much shorter periods of the order of 0.2–0.7 s, and they belong to the early, more subdued part of the BU spectrum. Had the ground motions in Bucharest been of the EC type, the greater effects of the earthquake should have been on the more rigid structures.

It is evident, therefore, that the adequacy of current lateral force code requirements derived from near-field ground motions, may be insufficient for flexible, low ductility structures wherever there exists the potential of a large, distant or intermediate-depth earthquake. This situation may arise more often than previously believed, particularly in the eastern Mediterranean region, and in fast developing cities at some distance from major throughgoing faults capable of producing large earthquakes.

Confirmation of central volcanoes off the Icelandic coast

The Icelandic shelf and slope region occupies much of the transition zone between the complex Icelandic hot spot and more uniform ocean-ridge areas to the north and south. This transition zone is relatively little known geologically, but in this communication we summarise some recent observations on the nature of its basement. It is well known[1] that the shelf is generally narrower off the eastern half of Iceland than off its western half. This is most obvious south of Iceland, where the shelf width changes suddenly at the eastern volcanic zone; the insular slope is also steepest off south-eastern and north-eastern Iceland. Recent geophysical surveys[1,2] in the southern and south-eastern shelf area have indicated the presence of an abrupt basement scarp now covered by sediments, 5–14 km inside the bathymetric shelf break (Fig. 1). This scarp is at least 1 km high and only a few km in mean width. No such basement scarp is indicated in comparable surveys conducted so far off western Iceland[1–3]; north-east of the island, detailed data is not yet available.

A causal relationship between this and other observed east–west asymmetries in the geology of Iceland, including the much greater uplift and erosion in eastern than in western Iceland since the Upper Tertiary, is likely to be found in differences in crustal thickness or upper mantle composition respectively east and west of the eastern volcanic zone. Similarly, the abrupt change in the chemistry of recent volcanics occurring north of Iceland[4] very close to the shelf break, may directly reflect changes in crustal thickness[5], rather than damming effects of the Tjörnes fracture zone on subcrustal flow[4].

Another point concerns the central volcanoes of Iceland, first described by Walker[6], which are of major significance in its geological evolution. Over 60 such centres, active or extinct, have now been identified on the island. From the results of geophysical surveys[3,7] it has been concluded that several central volcanoes occur on the insular shelf off eastern and western Iceland, and that the trace of the Icelandic hot spot in the North Atlantic may coincide with the greatest density of such centres.

In an attempt to confirm the occurrence of central volcanoes on the Icelandic shelf, we have dredged at three sites (Fig. 1) where topographic highs are associated with the major magnetic anomalies believed to be characteristic for such volcanoes. The dredging was carried out by the RV Hafthor, of the Marine Research Institute, in November 1975, and a collection of igneous rock boulders was recovered at each dredge site.

Those features of a dredge collection which might be used to indicate the presence of a central volcano include (1) a large proportion of acidic, intermediate or gabbroic rocks (2) rocks having suffered intense hydrothermal alteration, and (3) unusually magnetic and magnetite-rich rocks. Accordingly, the rock types in these dredge samples were identified in thin section, and their magnetic susceptibility and natural remanence were measured in core specimens. The results (to be published in more detail[8]) may be summarised as follows.

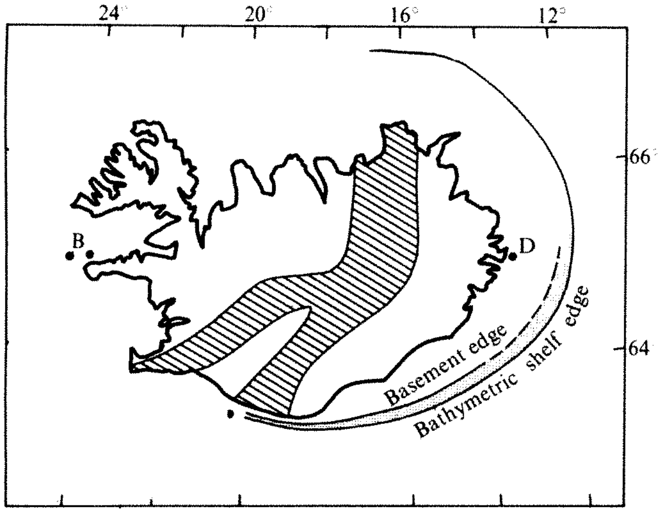

Fig. 1 Map of Iceland, showing the smoothed position of the upper edge of the steep insular slope off the eastern half of the island, and a major basement edge inferred from marine magnetic and gravity data off southern and south-eastern Iceland[1,2,7] to occur under shelf sediments. Both edges are indistinct between 64° and 65°N. Hatched areas: active volcanic zones in Iceland. B, D, Dredge localities.

Of the two dredge sites off western Iceland (20 km apart), one yielded six basalt boulders and six rhyolite boulders, while the other yielded 71 basalt and diabase boulders and two rhyolites. Alteration state and magnetic properties of these samples are similar to those found in lavas on shore.

At the Diönubodi dredge site 14 km off Gerpir promontory, eastern Iceland, the samples recovered were predominantly (21 out of 35) of acid and intermediate rock types, including granites, rhyolites, acid tuff, and andesites. Two samples contain epidote. The magnetic properties of this collection are also unusual: thus, nine specimens out of the 34 measured have volume susceptibilities exceeding 0.1 T A^{-1} m (8×10^{-3} G Oe^{-1}), compared with only 1% of the specimens in a collection from 740 Eastern Iceland basalt lavas recently measured by us.

We are confident that the Diönubodi dredge collection can only be derived from a local central volcanic complex, which also causes the large (up to 6,000 nT) magnetic anomaly[7] observed there. It is, furthermore, difficult to explain the high proportion of acid rocks at one of the western sites without recourse to similar conditions. These findings strongly support previous hypotheses[3,7] on the occurrence of other central volcanoes on the Icelandic shelf.

How do children learn the meanings of verbs?

ONCE children have begun to learn their native tongue, they acquire vocabulary at a remarkable rate. An intelligent 6-yr-old is able to recognise 13,000 words, and more than double that number 2 yr later[1]. According to orthodox linguistic theory, the learning of verbs and other relational terms ought to be difficult because, in addition to their meaning, they have 'selectional restrictions', which constrain the noun phrases that can occur with them[2]. A child must learn, for example, both the meaning of the verb 'fly' and the fact that it takes subjects which are restricted to denoting moveable objects. This linguistic theory has, however, been criticised, and it may be a misleading basis for a model of language acquisition since meaning and selectional restrictions can hardly be independent[3]. In particular, the subjects and objects that occur with a verb might help the child to infer its meaning, and likewise the meaning of a verb might help to define its possible subjects and objects.

In order to investigate such assumptions, we provided 15 young children (mean age, 3.10 yr) with an opportunity to learn some verbs. On each trial, the experimenter told a story to one of the children and acted it out with puppets. A typical story ran as follows: 'John stepped out of the boat and the water mibbed his trousers so he went home to change into some dry clothes. The water had mibbed his trousers right through so Simon made him some hot tea. But John dropped his cup and the tea mibbed over the floor'. The novel verb, mib, has a transitive meaning similar to that of soak and an intransitive meaning similar to that of spill—there is no single word corresponding to it in English, but it always occurred with a subject noun phrase denoting a liquid. The child heard the story four times: on the first two occasions the experimenter acted it out appropriately, and on the second two occasions the child attempted to do so. As a test of what the child had learned, he or she was presented with four items unrelated to the story (for example a female doll, some orange juice in a container, a car, a ball) and asked 'Which one can mib?' Only one item—the orange juice—is in accord with the selectional restrictions of the verb. Any child who made a correct choice was retested 7–10 d later. In this retrial, only the test was carried out: the child was simply asked to pick out the item that mibbed from a new set of four.

Four different stories were devised in order to test the children's ability to acquire four sorts of verb defined in terms of their selectional restrictions: animate subject, animate object, liquid subject, liquid object. Earlier studies of children's comprehension of sentences suggested that animate subject and liquid object verbs should be easier to learn than liquid subject and animate object verbs[4,5]. A fifth story was also used for reasons that will become apparent shortly. None of the novel verbs had any single semantic counterpart in English. They were based on five nonsense syllables, with association values of approximately 2.1 (ref 6), which were allocated to the stories in a counterbalanced way from one subject to another. Each child was individually tested with each of the stories in five separate sessions during the course of a morning. The order of presentation of the stories was randomised.

The children picked out a mean of 2.4 correct items on the five initial tests (with eight children performing significantly better than chance). There were 33% correct responses for animate subject verbs, 66% for animate object verbs, 60% for liquid subject verbs, and 46% for liquid object verbs. These differences fail to support the view that animate subject and inanimate object verbs should be easier to learn, and were not significant (Cochran's $Q = 2.42$, $P > 0.50$). A week later, the children who had responded correctly to a verb were retested with it, and the percentages of correct responses were: 76% for animate subject verbs, 66% for animate object verbs, 12% for liquid subject verbs, 28.5% for liquid object verbs. The animate verbs were significantly better retained than the liquid verbs (Fisher–Yates exact probability, $P = 0.01$, on the assumption that all the data were independent).

Selectional restrictions probably involve an inference about whether a particular referent is a possible subject of a verb, and so on[7]. Hence, in the case of a sentence such as, 'The Smiths saw the Rocky Mountains flying to California', a child who lacks some pertinent general knowledge about mountains or relative motion will be unable to make the required inference and may well conclude that the Rocky Mountains were flying. In order to test this hypothesis, a fifth story was constructed with a nonsense verb that selects subjects capable of movement. As a test of what had been acquired, the children were asked to act out two sentences: 'Jane saw the boat gebbing towards the ball', and 'John saw the house gebbing towards the park'. Their initial performance was 93% and 33% correct, respectively. When we retested the successful children a week later, performance was 100% and 50% correct, respectively. Evidently, it was easy for the children to learn that the subject of the nonsense verb denoted something that moved, but few children made the intended interpretation of the second test sentence. Its syntax suggests that the house is the entity that gebs and, in fact, 10 subjects attempted to move the house. They did not infer that the house cannot move with respect to the park. One subject, however, put the doll in front of the house with his hands in the air and explained: "He's stopping the house from gebbing to the park".

At least half the children learned something about the selectional restrictions on verbs from the stories they heard, which suggests that this experimental procedure is useful. But it does provide two clues to the meanings of the verbs: the accompanying actions and the linguistic context. A second study was accordingly carried out in which 14 children (mean age 4.3 yr) merely listened to the stories (4 times), which were not accompanied by any actions. Performance on the initial tests corroborated the results of the previous study: 11 subjects made two or more correct responses which, overall, were very evenly distributed across the four sorts of verb. There was also no significant difference, however, between the verbs on the retest a week later.

Young children are evidently capable of picking up incidental information about a variety of different sorts of verb. In previous studies of comprehension, selectional information has often been uncontrolled. For example, it has been found that 5-yr-olds tend to answer the question, 'Is this doll easy to see?', as though the doll were the subject of the verb. It remains unclear whether the response reflects a genuine syntactic bias[8] or merely the fact that the major selectional restriction of the verb clearly points to an entity with eyes.

Our results suggest that children are sensitive to whatever cues are available to meaning. They readily pick up selectional information about both animacy and liquidity. With hindsight, it might be odd if this tacit skill were exercised to a significantly different extent with such familar concepts. Their ability to retain newly acquired knowledge may, however, depend on its nature and on the sort of experience leading to its acquisition. The answer to our question does, indeed, seem to be that children learn the meanings of verbs rapidly, without their attention being deliberately drawn to them, and often in circumstances where the major cue is the selectional information provided by the sentence as a whole.

We thank David McNeill for his advice and also his son, Randy, who was the first subject to grapple with the Rocky Mountains flying to California.

Adoption study supporting genetic transmission in manic–depressive illness

Comparison of adoptive parents of persons with a psychiatric disorder with their biological parents provides a unique opportunity to separate the interacting aetiological roles of heredity and environment. We have conducted such a study in manic–depressive illness; the results strongly support the importance of genetic factors in the transmission of this disorder.

A genetic vulnerability to manic–depressive disorder has been demonstrated by family, twin, and linkage studies[1–4]. To our knowledge, this is the first report of an adoption study of affective illness, but research involving adoptive families has been done for schizophrenia and other psychiatric disorders[5–10]. Our investigation was carried out in Belgium because adoptive registers are available there, and the adoption agencies were willing to help us to obtain subjects.

Our subjects were the adoptive and biological parents of manic–depressive adoptees. There were three sets of controls: (1) the parents of manic–depressives who were not adoptees; (2) the adoptive and biological parents of normal adoptees, and (3) the parents of individuals who had contracted poliomyelitis during childhood or adolescence. This last group was designed to control for the effect on parents of bringing up a disabled child.

The group of affected offspring (that is, manic–depressive adoptees) was ascertained by systematically examining the medical records of five outpatient clinics and five inpatient services in the vicinity of Brussels. All admissions during a 5-yr period (1971–1976) were reviewed. Those persons who were designated as manic–depressive and who were described as having been adopted were interviewed by one of us (J.M.) to

confirm the diagnosis. We used a modified form of the semi-structured interview, Current and Past Psychopathology Scales (CAPPS) (ref. 11) and the diagnostic criteria of Feighner *et al.*[12]. Only persons who had bipolar illness (that is, had experienced both manic and depressive episodes) were accepted as probands. To meet our criteria, they also had to have been transferred to their adoptive homes before 1 yr of age and to have been raised by those parents until adulthood. The adoption agencies supplied the details on the dates of adoption of the offspring, and gave us the names of the biological parents. Municipal registers were used to locate all parents. We only accepted families in which at least three of the four parents were available and willing to participate.

Manic–depressive offspring who were not adopted were ascertained from admissions records of the same facilities as the adoptees, covering a similar time period. Psychiatrically normal adoptees were ascertained through the adoption agencies; these individuals were given clinical interviews and only those without psychopathology were accepted. Their biological and adoptive parents were traced by the same procedure as those of the experimental group. None of the adoptive parents were related to the biological parents. The poliomyelitis patients were ascertained through three paediatricians who had been treating them over a long period. The three groups of control offspring were selected out of the total number of possible subjects by matching them with the index population according to age, sex, national origin, religion, and socio-economic status. Table 1 summarises the ascertainment and demographic characteristics of the experimental and control groups.

All of the parents were interviewed by one of the clinicians, blind as to the adoptive and clinical status of the offspring. The same instruments and criteria were used as for the diagnostic confirmation of their offspring. The interviews took place in the parents' homes unless the parents preferred to meet at the local centre. The greatest distance travelled was 52 miles from Brussels, indicating a low mobility of this sample. Two and a half to three hours were spent with the parents for the psychiatric interview. The parents were instructed at the outset not to speak about their children until specifically asked. Demographic characteristics of the parents are summarised in Table 2.

The major finding of this investigation is that psychopathology in the biological parents is in excess of that found in the adoptive parents of the same manic–depressive offspring (Table 3). If we focus on disorders which we may call the affective spectrum, namely, bipolar affective disease (episodes of mania and depression), unipolar affective disease (psychotic depressions without mania), schizoaffective psychosis (schizophrenic and affective episodes), and cyclothymia (cyclothymic personality), the difference is significant at the level of $P < 0.025$ ($\chi^2 = 5.10$). Previous genetic studies by us and others support the inclusion of unipolar and schizoaffective disorders as genetically related to bipolar illness when they are found in close relatives of bipolar patients[2,4,14–16]. If we include other forms of psychopathology, the difference is highly significant ($\chi^2 = 7.29$, $P < 0.01$). The frequency of non-affective psychopathology was no higher in the biological parents of bipolar adoptees (9%) than in those of normal adoptees (16%), indicating that it is by virtue of the affective disorders that the former differ from the latter (31% compared with 2%).

Table 3 also shows that the degree of psychopathology in the biological parents of manic–depressive adoptees is similar to that of the parents of the non-adopted manic–depressives, and that the rate of psychiatric disorder in the adoptive parents of the experimental group is similar to that of the adoptive parents of the normal offspring group. The degree of total psychopathology in the biological parents (of normal offspring) who gave their children for adoption is slightly greater than in adoptive parents who brought up those same individuals. It is

‡ $x^2 = 7.29, P < 0.01.$

worth noting that this difference is due to an excess of alcoholism and sociopathy in the former group. Finally, the degree of psychopathology in the parents of polio patients is in the same range as in both groups of adoptive parents. All these findings support our conclusion that our experimental sets of parents are truly representative of the degree of psychiatric disorder which is present respectively in those parents who bring up and those who contribute genetically to manic–depressive individuals.

Another finding of interest is that no father-to-son transmission of manic–depressive illness was seen in our entire sample. This is consistent with a sex-linked model of bipolar illness, which has been suggested by some previous genetic studies[2–4]. Finally, bipolar illness, as would be expected, had an early onset in all parents in whom it was present; however, the onset of unipolar illness in the adopting parents occurred, in every case, after the onset of manic–depressive illness in their children, whereas in the biological parents, onset of unipolar illness occurred almost always previous to the onset in their children. This observation strengthens the genetic hypothesis by suggesting that the adoptive parents' unipolar illness might be more reactive and less severe than that of their biological counterparts; early onset is often considered to be an index of severity in psychiatric disorder.

In summary, we found a greater degree of psychopathology, particularly of affective illness, in parents genetically related to manic–depressive probands than in parents who adopted and raised these same individuals. The results demonstrate the importance of genetic factors in the aetiology of manic–depressive illness.

We thank Judith Klotz for assistance and Professor E. Sand and Dr P. Linkowski for their contribution to the study. This work was supported by the New York State Department of Mental Hygiene and by a grant from the University of Brussels.

Number of trophic levels in ecological communities

ECOLOGICAL food chains are typically short, consisting of not more than four or five trophic levels. This is usually explained by a reduction in the energy which is available to successive links in the food chain[1,2]. In contrast, we believe that the number of trophic levels is constrained by population dynamics and not by ecological energetics.

In the extreme, food chains must obviously be limited by the flow of energy. Slobodkin's[2] hypothetical predator occupying a trophic level higher than twenty and needing a continent to support it is a dramatic example. However, if food chains are primarily limited by energy they should be longer in more productive ecosystems; for example with an ecological efficiency[2] of approximately 10%, trophic levels should increase at the rate of one for each tenfold increase in the energy entering the system. This does not seem to be true. Primary productivity ranges over at least four orders of magnitude in terrestrial ecosystems, over three for aquatic systems[3]; yields of fish and the productivity of animal populations range over five or more orders of magnitude[4,5]; yet the number of trophic levels supported by these particular plant and animal populations does not seem to be closely correlated with the productivity of the base of the food chain. Food chains are not noticeably shorter in barren Arctic and Antarctic terrestrial ecosystems[6,7] compared with a productive tropical savannah[8] or the fish guilds of a tropical coral reef[9].

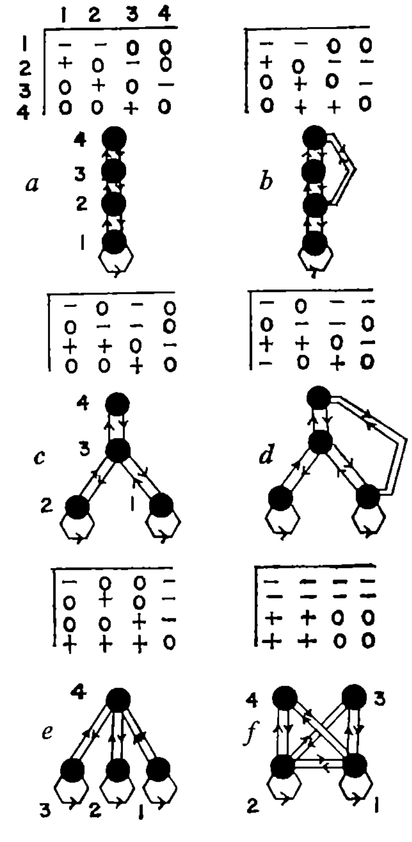
One explanation for short food chains is that it is advantageous to feed low in the chain, where more food is available. The effects of body size[1], or the seasonality and predictability of resources may also be important[10,11]. However, the dynamically fragile nature of long food chains does not seem to have been discussed.

Consider a system of n interacting species described by equations of the form

$$\frac{dX_i}{dt} = X_i\left(b_i + \sum_{j=1}^{n} a_{ij}X_j\right) \equiv F_i \qquad (1)$$

where X_i is the population size and b_i the instantaneous rate of growth of the ith species, and a_{ij} is the *per capita* effect of the

Fig. 1 The matrices show whether the species along each row has a positive (+), negative (−) or no (0) effect on the species in each column at equilibrium; the figures below indicate these relationships diagrammatically.



jth species on the ith species. We used equation (1) to construct model food chains of varying length and complexity, and judged their feasibility by whether or not they were locally stable, and if they were, how long they took to return to equilibrium after a disturbance (the 'return time'). Long return times imply an increased probability of extinction in the real world[12–14]. The dynamics of equation (1) near equilibrium are determined by the eigenvalues of a matrix which is the Jacobian

$$\frac{\partial F_i}{\partial X_j} \begin{matrix} j = 1, n \\ i = 1, n \end{matrix}$$

evaluated at equilibrium. A system which contains non-negative eigenvalues will be locally unstable, while the return time of a locally stable system will be roughly proportional to the reciprocal of the largest eigenvalue. Formally

$$\text{Return time} = -1/\text{Real}\,(\lambda_{\max}) \text{ (for all } \lambda < 0)$$

In general, as the number of species in a model ecosystem increases, the probability of local stability decreases[15]. But it is possible using differential equations to construct linear food chains of any length that are locally stable (Fig. 1*a*), and Maynard Smith[16] has argued that "the lengthening of food chains will not by itself cause instability". This view gives a distorted impression of what is biologically feasible, because as the number of trophic levels increases, so do return times.

We have followed established practice[12,17–19], and investigated eigenvalues of matrices whose elements are random variables subject to constraints of sign and absolute magnitude. The possibilities investigated are shown in Fig. 1. Parameter values were set by the biological details implied by the model[13]. The diagonal elements of the Jacobian are $X_i^*a_{ii} = -b_iX_i^*/K_i$ where X_i^* is the equilibrium population of the ith species, and K_i its equilibrium in the absence of all other species. Since the X_i^* cannot exceed K_i these values will be in the interval $(0, -b_{ii})$ (the b_{ii} were set equal to 1 in each species). The off diagonal elements are also of the form $X_i^*a_{ij}$ where the sign of a_{ij} will depend on whether i is feeding on j or vice versa, or whether i and j are competitors. For predator–prey interactions (Fig. 1 *a–e*) a_{ij} is the number of new predators produced per prey eaten; the latter will usually be much larger than the former. The X^* will also differ, since predators are likely to be fewer than their prey at equilibrium. The effects of the predator on the prey population were therefore uniformly distributed on the interval $(0, -10)$ and the effects of the prey on the predator on the interval $(0, +0.1)$. For competition (Fig. 1*f*) $X_i^*\cdot a_{ij}$ is the magnitude of the interspecific competition. This will usually be less than the absolute value of the intraspecific competition $(X_i^*\cdot a_{ii})$ and was uniformly distributed on the interval $(-X_i^*\cdot a_{ii}, 0)$. For each of the six configurations of signs shown in Fig. 1 nearly 2,000 matrices were created whose elements satisfied these general constraints. Figure 2 shows their return times. (Results were qualitatively the same in 1,000 initial simulations in which the matrix elements had absolute values between zero and one, suggesting that they are not sensitive to the assumptions about the magnitude of the matrix elements.)

Consider first the models without omnivores (Fig. 2*a*, *c*, *e*). As the number of trophic levels increases, so do return times. For two trophic levels, nearly 50% of the models had return times less than or equal to five; with three trophic levels, this drops to 5% and with four, to less than 1%. Figure 2 also shows the percentage of models where return times exceed 150. With two trophic levels this is very small (0.1%), but is 9% and 34% respectively with three and four trophic levels.

A two-species system with one predator and one prey can be examined analytically. Here there are as many species as trophic levels, analogous to model (*a*) of Figs 1 and 2. About 70% of the two-species models had return times less than or equal to five—a considerably larger percentage than is found in model (*a*), but comparable with the situation in model (*e*). Hence, models with different numbers of species and the same number of levels, and models with the same number of species but different numbers of levels lead to similar conclusions. We suggest that this increase in return times with an increasing number of trophic levels will play an important part in limiting the lengths of food chains subject to the perturbations of the real world.

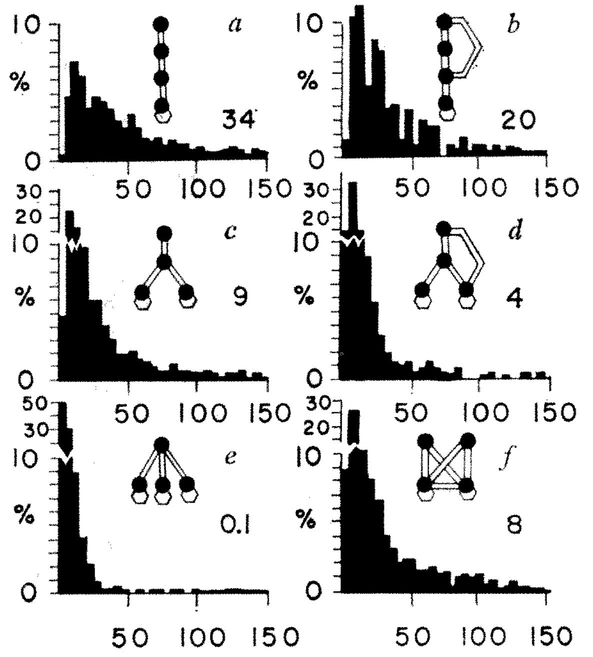


Fig. 2 The distribution of the reciprocals of the largest eigenvalues (a measure of return times) from nearly 2,000 matrices of each configuration. The number on each histogram is the percentage of those reciprocals which have a value greater than 150.

With omnivores, 78% of both the three (Fig. 1*d*) and four (Fig. 1*b*) trophic-level models are unstable. Return times in the remaining 22% are illustrated in Fig. 2*b* and *d*, which show that omnivores do not affect the conclusion that longer food chains imply longer return times; however, the distributions are shifted slightly towards faster values. Whether or not the addition of omnivores (further complexity) contributes to the 'stability' of a system then depends on how these results are evaluated. For systems assembled at random, omnivory increases the probability of instability; however those that are locally stable have faster return times, and in this sense are more stable. This paradox does not seem to have been mentioned in studies on 'complexity' and 'stability' in model ecosystems.

Figure 2*f* includes competitive effects in the lowest trophic level. As expected[20], 53% of the models were unstable but the return times of the remainder were no greater than in model (*c*), a three-trophic-level model, which lacks the destabilising factor of competition. However, it is known that a 'pure' competition community (one trophic level) of n interacting species may have more than one locally stable equilibrium[21]. It is not clear how the addition of higher trophic levels would influence the existence of, and rates of return to alternative equilibria; further work is required on this point.

We have only considered one type of model (differential equations) and one aspect of their dynamic behaviour (return time). It is easy to construct very different models, implying different biological details, and with very different behaviours. It is therefore encouraging to note that in a discrete generation (difference equation) model of an insect host–parasitoid interaction (two trophic levels), large areas of stable parameter space disappear when a third trophic level (a hyperparasite) is added[22]. This reinforces our view that the number of trophic levels in ecological communities is determined not by ecological energetics, but by population dynamics.

We thank John Beddington, Charles Free, Robert May and Stuart McNeill for helpful discussion.

Large benthic microbial communities in sulphide biota under Peru–Chile Subsurface Countercurrent

BENTHIC observations off the coast of Chile have consistently disclosed the presence of large coherent microbial communities living at depths of about 50–280 m in the H_2S-containing sediments of the shelf in contact with the deoxygenated waters of the Peru–Chile Subsurface Countercurrent (SCC). Similar observations were also made off Peru in 1969 by Gilbert T. Rowe, and in 1976 by G. T. Rowe and John Waterbury of Woods Hole Oceanographic Institution. The microflora, which has only been reported once before in the literature[1], has been known for years by the local fishermen who call them *estopa* (Spanish for uncleansed wool or fiax) due to the filamentous appearance of its main components. In this report I describe this massive microbial community which includes organisms typical for sulphide biota, and may have unsuspected importance in the ecology and economy of the sea off western South America.

Repetitive quantitative grab sampling off Concepcion, Chile (36°35′30″S, 73°04′20″W) at 60-m depth, indicated biomass of 106 g (wet weight) per 0.1 m^2 for the microbial component, while the benthic infaunal biomass in the same sample attained only 11.5 g (wet weight) per 0.1 m^2 (Peterson 0.1-m^2 sample washed through a 0.25-mm^2 sieve). Preliminary examination of the community has shown that it consists of many kinds of prokaryotes. The main constituent, however, is typically large filaments of *Thioploca* spp. This genus of gliding bacteria has not been previously recorded in open oceans. The *Thioploca* spp. fall clearly into three groups according to their cell diameter: (1) 30–40 μm, (2) 15–20 μm, and (3) 2.5–5 μm, (Dr Maier, Ohio University, personal communication). Other members of the community are *Oscillatoria*-type blue-green algae (cyanobacteria), flexibacteria (probably of the genus *Chlorophlexis*) and various other forms of bacteria.

The *Thioploca*-like forms appear as many individual filaments within a common sheath (Fig. 1, inset) forming large, whitish-yellow, twine-like structures that attain 100–500 μm in diameter and several cm in length, therefore perfectly visible to the naked eye (Fig. 1). Off the Bay of Concepcion, where most of the recent observations have been carried out, the sediments consist of a loose superficial yellowish-brown layer of a few mm thick, an intermediate layer of black H_2S-containing sediment about 8 cm thick, and a lower dark-brown layer of sticky compacted mud[1]. The filamentous microbial material occurs in the upper two layers, giving the sediment a soft, spongy texture. The sediment, a diatomaceous mud, also contains large quantities of assorted organic debris such as fish scales, fish bones, faecal pellets, few shell fragments, empty polychaete tubes and some terrestrial vegetal remains.

Although the genius *Thioploca* is classified among the colourless Beggiatoaceae[2], some species of the genus contain a greenish blue pigment and have therefore an uncertain taxonomic relationship to the *Beggiatoa*[3]. Ethanol extracts from seawater-washed filaments have given absorption spectra typical for chlorophyll *a*, with major peaks at about 410 nm and 670 nm; however, it is probable that this pigment is associated with oscillotorian cyanobacteria known to be components of this community. The gliding of independent filaments occurs within their common sheath at speeds of up to 12.5–25 μm min^{-1}.

Whatever the taxonomic position of these *Thioploca*-like forms, their large standing-crop suggests an important role in the ecology of the upwelling biome off southwestern South America.

The SCC, a wedge-shaped water mass distributed between northern Peru and southern Chile (to about 41°S), is characterised by relatively high salinity and temperature, and extremely low oxygen content, typically under 0.1 ml O_2 per l. Nutrient concentrations are high[4–6].

The presence of filamentous microbial associations should be looked for in other parts of the world where similar oceanographic conditions exist. Recently a single *Thioploca*-like filament was observed in a small sediment sample collected off Walvis Bay in

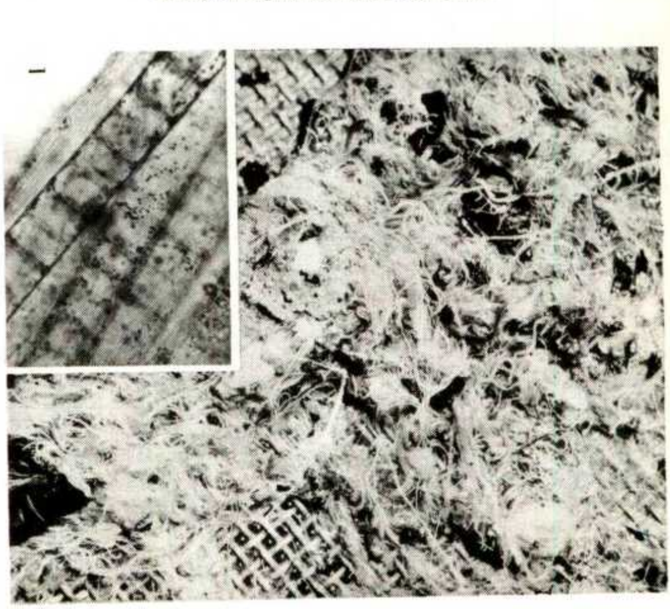

Fig. 1 Filamentous microflora deposited on a 1-mm^2 mesh 12-inch diameter geological sieve after washing a 0.1 m^2 Petersen grab sediment sample collected at 100-m depth off the Bay of Concepcion, central Chile, October 7 1975. At 90 m salinity was 34.54‰, temperature 9.71 °C, and dissolved oxygen 0.54 ml l^{-1}. Inset, photomicrograph of portion of *Thioploca*-like form no. 1. The common sheath and four cell-chains containing intracellular sulphur granules are visible. Cell dimensions are 2436 μm diameter and 3036 μm length. Bar represents 10 μm.

south-western Africa (J. W. Farrington). In this upwelling region a mysterious benthic 'slimy grass' has been reported at depths of about 90–130 m (ref. 7), occurring with a low-oxygenated subsurface countercurrent impinging against the shelf[8].

The coincidence of the depth distribution of the microbial community off Chile and that of the principal shrimp (both penaeid and galatheid) and hake fishing grounds[9], strongly suggests a possible trophic relationship in view of the fact that most of the standing-crop therein seems to be made up of filamentous bacteria.

Drinking behaviour induced by intracranial injections of eledoisin and substance P in the pigeon

THE only peptide known which rapidly and consistently elicits a specific behavioural response when injected into the brain is angiotensin II, which in picomole doses causes reptiles, birds and mammals to seek out and drink water[1]. But, there is evidence to suggest that other peptides such as substance P may also participate in the control of brain function and behaviour. Substance P is distributed throughout the mammalian peripheral and central nervous system, particularly in myenteric plexus, sensory afferent pathways, hypothalamus and substantia nigra[2]. In the human brain regional concentrations as high as 0.5×10^{-9} mol per g wet tissue have been reported[3]. Substance P is a member of a family of peptides with similar pharmacological properties and which also includes eledoisin, an undecapeptide obtained from the salivary glands of certain Mediterranean cephalopods[4]. These peptides share a similar amino acid sequence at the C-terminal end (Fig. 1). Both eledoisin and substance P stimulate nerve cell activity in vertebrates and invertebrates and may act as regulators of neural activity[5], but no specific behavioural effect of these peptides has yet been reported. We report here that eledoisin and substance P elicit vigorous drinking when injected into the brain of conscious pigeons.

At a preliminary operation intracranial cannulae (outside diameter (o.d.) 0.6 mm) were implanted stereotaxically in male and female pigeons (*Columba livia*, 300–450 g) under Equithesin anaesthesia (3.0 ml per kg body weight). The cannulae terminated in the lateral or third ventricle, preoptic area, lateral hypothalamus or striatum. The pigeons were allowed at least one week to recover from the operation before testing began. The injections were made in conscious birds through stainless steel tubing (o.d. 0.3 mm) inserted into the implanted cannulae and projecting 1 mm beyond the cannula tip into the brain tissue. All drugs were dissolved in 0.9% saline and injected in volumes of 1 μl over 10 s. The highest dose of eledoisin was injected in 10 μl because of its low solubility. The pigeons were returned to their home cages immediately after injection where food, water and mineral grit were available. Only one drug was tested per day, with at least a 2-d rest between tests. The order of testing was random. The drugs injected were eledoisin (Farmitalia), eledoisin-related peptide, substance P, Asp^{1}Ile^5-angiotensin II, arginine vasotocin (all from Bachem), vasopressin (Pitressin, Parke-Davis), bradykinin (Sigma) and L-glutamate (Sigma).

Intracranial injections of as little as 10^{-11} mol eledoisin consistently caused pigeons to drink water. The drinking was vigorous but completely normal, and usually began within 1 or 2 min after injection. The mean latency ($\pm$s.e.m.) in 13 pigeons in response to 10^{-10} mol of eledoisin was 1.5 ± 0.2 min. The amount of water drunk was dose dependent and was large (Fig. 2). Intracranial injection of 10^{-9} mol eledoisin caused pigeons to drink more than they would normally ingest during the entire day, usually in a period of less than 5 min. The response was repeatable from day to day and always specific to drinking. None of the birds ever ate or engaged in any other behaviour consistently after injection. When the water spouts were removed from the cage the pigeons repeatedly looked around the cage for water and pecked frequently at the hole where the water spout normally projected. Immediately the spout was replaced they drank vigorously. When drinking was prevented eledoisin did not cause increased body water losses, as measured by changes in body weight, and there were no changes in cloacal temperature. Intravenous injections of 10^{-10} or 10^{-9} mol of eledoisin did not cause pigeons to drink ($N = 5$), indicating that the effect of intracranial injections was not due to leakage from the brain.

Since this drinking response was identical to that which we observed following intracranial injections of angiotensin II in the pigeon[6], we compared the relative potencies of these two peptides. On a molecule per molecule basis eledoisin was only about one order of magnitude less potent than angiotensin II (Fig. 2). Thus in the pigeon eledoisin is as active a dipsogen as carbachol is in the rat[1].

The C-terminal hexapeptide fragment of eledoisin (eledoisin-related peptide) and substance P also caused pigeons to drink when injected into the brain. These peptides were less active than eledoisin, but again the response was specific to drinking and the amount of water drunk was significantly greater than that following control injections of 0.9% saline (Fig. 2). On the other hand, intracranial injections of vasopressin (10^{-12},10^{-11} mol), vasotocin (10^{-11},10^{-9} mol), bradykinin (10^{-10},10^{-9} mol) or L-glutamate (10^{-10},10^{-7} mol) had no significant effects.

Eledoisin caused drinking in all brain regions sensitive to the dipsogenic actions of angiotensin II. These included the lateral ventricle ($N = 3$), third ventricle ($N = 3$), preoptic region ($N = 6$) and lateral hypothalamus ($N = 4$). There were no significant differences in the response to eledoisin from these four areas but intakes tended to be highest following preoptic or third ventricular injection. Two pigeons with cannulae in the neostriatum which did not pass through the lateral ventricle failed to drink to

Substance P	Arg - Pro - Lys - Pro - Gln - Gln - Phe - Phe - Gly - Leu - Met (NH$_2$)

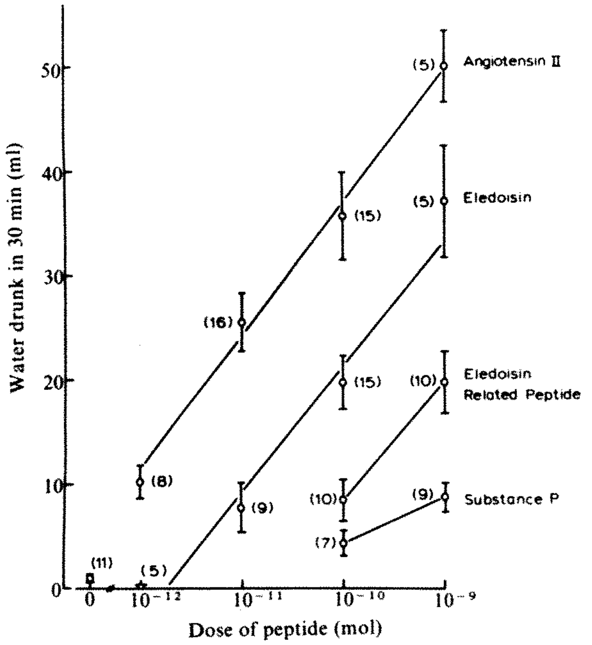

Fig. 2 Mean amounts (±s.e.m.) of water drunk in 30 min (no. of birds tested in parentheses) following intracranial injection of different peptides. Controls received 1 μl 0.9% NaCl. Regression lines are shown for angiotensin II and eledoisin.

eledoisin or angiotensin II. One pigeon with a striatal cannula which did pass through the lateral ventricle drank to injections of the peptides, probably because of reflux of the injected material into the ventricular system as has been shown for angiotensin II injections in the rat[7].

The similar time course and dose-response relationship of drinking following intracranial injections of angiotensin and eledoisin in the pigeon and the similar neuroanatomical distribution of sensitive brain sites suggest a similar or common mechanism. It is unlikely, however, that these two peptides are activating the same receptor site, because eledoisin is structurally so very different from angiotensin II and because we have found that the receptor sites for angiotensin-induced drinking in rats and pigeons are highly specific for the angiotensin II octapeptide. Only slight modifications or removal of amino acids in the angiotensin peptide chain, particularly at the C-terminal end, severely reduce or even abolish activity altogether[8,9]. Other peptides such as vasopressin, vasotocin or bradykinin all fail to stimulate drinking in the pigeon.

Eledoisin and substance P are potent stimulants of neuronal activity[10], but a nonspecific activation of nervous tissue cannot explain the consistent and specific behavioural response observed here. Drinking was elicited by injection of these substances into several different brain regions which also contain the neural elements of many other behavioural functions. Furthermore, intracranial injections of glutamate, another potent excitatory substance, did not cause pigeons to drink.

This is the first demonstration that eledoisin and substance P can elicit a specific and complete behavioural response when injected into the brain. What is surprising is that this response should be identical to that elicited by angiotensin II, the only other peptide known to have such a pronounced behavioural effect. Angiotensin II is a potent vertebrate hormone that is released in response to extracellular fluid losses and has many actions which contribute to the restoration of body fluid balance[11]. The significance of the drinking response to eledoisin and substance P in terms of body fluid regulation remains to be determined.

Cells selective to binocular disparity in the cortex of newborn lambs

In the nineteenth century there was a vigorous controversy over the role of visual experience in the development of stereoscopic depth perception[1,2]. Recent neurophysiological findings suggest that certain cells in the visual cortex of cats[3,4], monkeys[5] and sheep[6] may provide the neural basis for stereopsis. Each cell is driven optimally by a stimulus at a certain distance from the animal, and different cells prefer different retinal disparities corresponding to objects at various distances. In cats, the neural pathways from the two eyes to individual cortical cells are labile and may be modified by visual deprivation during the first few weeks of life[7–10]. The visual cortex of the newborn kitten is immature and disparity selectivity appears only after exposure to a normal visual environment[11]. We find, however, that neither of these two conclusions is true of lambs.

It has been suggested that the neural mechanisms underlying stereopsis require visual experience for their development[11–15]. 'Plasticity' of binocular correspondence was observed by Schlaer[16] and was thought to account for the preservation of correspondence in spite of changing interocular geometry during development[14]. Newborn animals (including lambs) will avoid a 'visual cliff'[17,18], but it is unclear whether stereopsis is involved, particularly since chicks and rats will continue to avoid the cliff even with one eye closed[17]. Good depth judgment would be of obvious survival value in the wild, where a 1-d-old mountain lamb will avoid a ravine[19].

We have begun to investigate the possible role of visual experience in the development of stereopsis by recording from the visual cortex of lambs. In adult sheep (and goats) a substantial number of cells, especially in V_2, can be driven only by a binocular stimulus at a particular disparity. In V_2, the optimal vertical disparities are close to zero but a wide range of horizontal disparities (about ±4°) occurs[6]. Our strategy was to look for such depth-sensitive cells in the visual cortex of newborn lambs which have had no visual experience. Lambs are born robust and with clear optic media, which makes them very suitable for studying the development of disparity detecting mechanisms, especially since large horizontal disparities occur in the adult.

Six animals (five newborn lambs and one newborn kid) were used. Three were born and kept in complete darkness, and recorded from on the first, fifth and sixth days after birth. The other three were born in the light (albeit moonlight), kept in normal lighting, and recorded from within 21 h of birth. They were anaesthetised initially with 2% halothane in oxygen and later maintained on intravenous pentobarbitone (0.5 mg per kg body weight per h) and a N_2O/O_2 mixture (60%, 40%). This dosage was sufficient to give full surgical anaesthesia in newborn lambs, and larger doses caused respiratory arrest. Tubocurarine (0.1 mg per kg per h) and gallamine triethiodide (3 mg per kg per h) were used as paralysants to reduce eye movements. (For details see ref. 6.)

Tungsten-in-glass microelectrodes with impedances of 1–5 MΩ at 1,000 Hz were used[20]. Visual stimuli were usually hand-held targets moved against a screen 90 cm from the eyes and the separate monocular receptive fields were drawn on a tangent screen. For most of the units we also tested the effect of varying the retinal disparity by means of a Risley prism in front of the left eye. Units and background activity were tested once every 100 μM or so of electrode descent.

The positions of the eyes were monitored using a Fison indirect ophthalmoscope. The projections of the optic disk and vertical retinal artery were plotted on extensions of the tangent screen. Hence eye movements greater than 0.5° could be detected and corrected for.

Although the visual mapping on the cortex sufficed to distinguish V_1 and V_2, we identified the needle tracks histologically. Of the 231 units whose responses we tested, 30 were in V_1, 192 were in V_2, and 9 were not reliably located : 119 of the V_2 units were from lambs with no visual experience whatsoever. Here we describe only the units in V_2.

The results were clear-cut. Almost all the units were visually responsive, and more than 95% were sharply tuned to orientation. There was no noticeable difference in the proportion of tuned cells or in their sharpness of tuning compared with the adult. Most of the units responded much better to a moving oriented bar than to a moving spot and those which would respond to a flashed bar were selective to its orientation. In this sense they were truly orientation selective rather than direction selective cells. Also the cells seemed to be arranged in 'orientation columns' and systematic changes in orientation could be seen as the electrode crossed several columns (compare with baby monkey[22]). Figure 1 illustrates one such 'orientation sequence' from the very first penetration made in one of our newborn lambs. The orientations of the receptive fields of individual binocular neurones were determined separately through each eye, and were found to be precisely matched. Thus, in lambs, at least, there is no basis for the suggestion that the alignment of the optimal orientations in the two eyes requires visual experience[15,21].

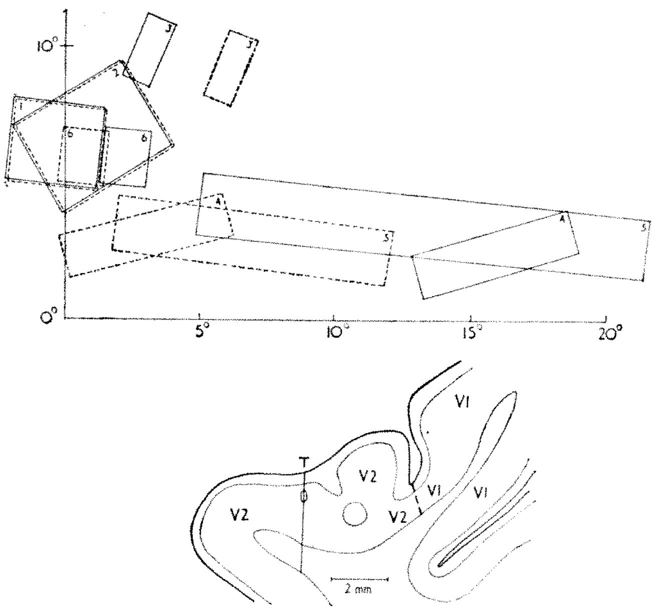

Fig. 2 The monocular receptive fields, through each eye, of the single units recorded in a penetration through V2, illustrating the occurrence of binocular disparities. This particular lamb was born 21 h before the start of the experiment, but it had less than 12 h of visual experience. Comparable results were obtained in a lamb with no visual experience whatsoever. The zero vertical meridia of the two eyes have been aligned, so the receptive fields of zero disparity cells are exactly superposed. The fields of the left eye are shown by discontinuous lines, and the numbers indicate the order in which the units were recorded. It can be seen that the disparities were purely horizontal and spanned a very large range on account of two units with unusually large (up to 13°) uncrossed disparities. We confirmed these disparities by tracking back and down again with the electrode, and we checked the eye positions after each large change of disparity. Also, the orientations of the receptive fields are the same for the two eyes. The inset shows the position of the electrode track (T), including a lesion, in V2. The V1/V2 border has been estimated by comparing the section with one 1 mm posterior in which the site where the visual map reversed was found with five electrode penetration.

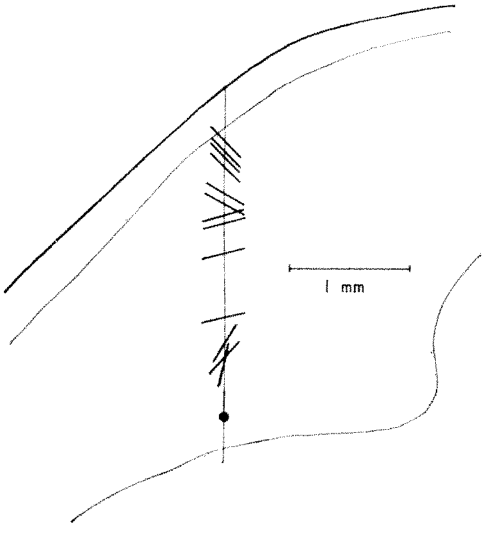
Fig. 1 An orientation sequence. The optimal orientations of 13 single units are plotted at the depth they were recorded in a penetration through V2. The only other unit recorded was not clearly orientated, and its position is marked by a filled circle. Clearly, the optimal orientation changed monotonically as the electrode advanced through the cortex, which suggests that the systematic organisation of orientation columns which occurs in the adult was already present. This lamb was born in complete darkness a few hours before the experiment, and its eyes were first exposed to light a few minutes before the start of this, the first penetration.



The receptive field properties did not differ noticeably from those in adults, and simple, complex and hypercomplex cells could all be found (as in the cortex of newborn monkeys[22]). There was one exception, however: 16 units were found for which the response was excitatory from one eye and strongly inhibitory from the other, with greatest inhibition at zero disparity. We have not so far found such units in adult sheep. The separate monocular fields of binocular neurones could be mapped on the tangent screen, and variations in binocular disparity (that is, the range of 'scatter' of receptive field disparities) could be precisely determined (Fig. 2). The most frequent disparity was taken to be zero. In three of the animals there was clear evidence of horizontal disparities of up to ±4°, but in one animal there were two cells with exceptionally large disparities (Fig. 2). The range of vertical disparities was close to zero in all six animals. Disparity 'tuning' curves could be obtained for many of the cells by varying the strength of the prism in front of the left eye. The peak of the tuning curve usually corresponded to what one would expect from actually measuring the angular distance between the centres of the monocular receptive fields. Hence cells selectively 'tuned' to a large range of non-zero disparities, as well as zero, were observed. These results cannot have been seriously contaminated by eye movements, since the positions of the eyes were monitored to within 0.5°, and the disparities were much larger than this. Furthermore, on some occasions we withdrew the electrode and drove it down the track again, and the same disparities were found at the same depths.

There were interesting differences between the V_2 binocular neurones of newborn lambs and those seen in the adults (more than three months). In adults most of the neurones give a strongly facilitated response to a binocular stimulus at the optimal disparity and many are true 'and-gates', not having discernable monocular receptive fields. In newborn lambs, however, *all* the binocular neurones could be independently driven through either eye and the degree of binocular facilitation or 'synergy' was considerably less than in the adult. The binocular facilitation in a normal seven-week-old lamb in which we recorded from 36 units was intermediate between that in the adult and in the newborn lamb. Whether the conversion of immature binocular neurones into true 'and-gates' requires visual experience, remains to be determined. The appearance of additional inhibitory mechanisms may be required for this.

In visually naive kittens, Pettigrew[11] found that the neurones were not selective to disparity and yet showed binocular facilitation at least as great as in the adult. This is the opposite of what we have found in lambs, where many of the cells were tuned to disparity, but the binocular enhancement was substantially less than in the adult. While several authors[9,11,14-16] have suggested that visual experience may have an active role in organising the feature-detecting properties of cortical neurones, there seems little need for this in the lamb, for we find that in virtually all the cells in V_2, the following are all specified by a genetic mechanism: (1) orientation selectivity; (2) organised 'orientation columns' and systematic changes in orientation tuning (orientation 'sequences'); (3) interocular matching of orientation selectivity, and (4) 'hypercomplex' type receptive field organisation. Most importantly, we have found that disparity selectivity is present at birth. This confirms Hering's theory[1] that the establishment of correspondence between disparate retinal areas does not require visual experience, although the progressive increase in the degree of binocular facilitation may turn out to require visual experience.

We thank Mrs Pat Donaldson for preparing the histological material, Mrs Vivienne Harris for technical assistance and Mr Robert King for providing visually inexperienced lambs.

Early hyperthyroidism alters the distribution of mossy fibres in the rat hippocampus

Daily injections of thyroid hormone initiated on the day of birth and continued for several weeks, significantly accelerate the differentiation of cerebellar granule cells[1-3], which are formed after birth[4]. Since most of the hippocampal granule cells are also generated postnatally, early hyperthyroidism was chosen as a means of studying possible mechanisms involved in the formation of synapses between granule cell axons (mossy fibres) and pyramidal cell dendrites. This note provides the light microscopic demonstration, with the Timm silver sulphide method[5], that hyperthyroidism in the rat consistently results in the formation of ectopic hippocampal mossy fibres. Electron microscopic and Golgi studies are in progress and will be published separately.

Basic mechanisms governing the formation of neuronal circuitries are as yet poorly understood. The spatial segregation of afferents along defined regions of the postsynaptic surface in neurones such as the cerebellar Purkinje cells and hippocampal pyramidal and granule cells indicate a high degree of specificity during neural ontogeny. At present, it is unclear how intrinsic neuronal properties, temporal factors, specific affinities and recognition processes interact in such development. The strict segregation of afferents along the pyramidal cell surface, in the hippocampus, first clearly conceived by Cajal[6] and further explored by Lorente de No[7], as well as the unique synaptic relationship between mossy fibres and the large protuberances (or 'excrescences') on the apical dendritic shaft of the pyramidal cell, make this an excellent region to study synaptogenesis, especially the relative parts played by the pre- and postsynaptic elements[8]. Genetically associated variations of this system have recently been reported in the mouse[9].

Since the synaptic boutons of the mossy fibres contain a metal (most likely zinc)[10], which can be stained histochemically using the Timm silver sulphide procedure[5], an easy and specific bulk method is available for light microscopic screening of large numbers of sections with respect to alterations in the distribution of granule cell axons. Hooded rats (males, 8 per litter) were made hyperthyroid by the subcutaneous injection of daily doses of 5–15 μg L-thyroxine in 0.1 ml physiological saline from the day of birth until day 15. Control animals were injected daily with 0.1 ml physiological saline during the same period. All animals were killed 30 d postnatally, by cardiac perfusion with 1.19% sodium sulphide and 5% polyvinyl pyrrolidone (R/P) in 1 l of 60% ethanol, preceded by a short prewash with physiological saline under choral hydrate anaesthesia. Brains were dehydrated, embedded in Paraplast, and sectioned serially along the horizontal plane. Slides were stained using Timm the silver sulphide method for the histochemical visualisation of mossy fibres as described extensively by others[5,9,11]. A total of eight hyperthyroid and eight control animals were used in this study, but more than 20 hyperthyroid animals have been examined, when rats injected with thyroxine according to different schedules are included.

In controls, as in the normal albino rat, the mossy fibres pass into the hilus of the fascia dentata, then course along the pyramidal cell layer largely transverse to the septotemporal axis of the hippocampal formation[7,12,13]. Most of these axons synapse *en passant* with the excrescences on the apical dendrites of pyramidal cells. These fibres form the suprapyramidal

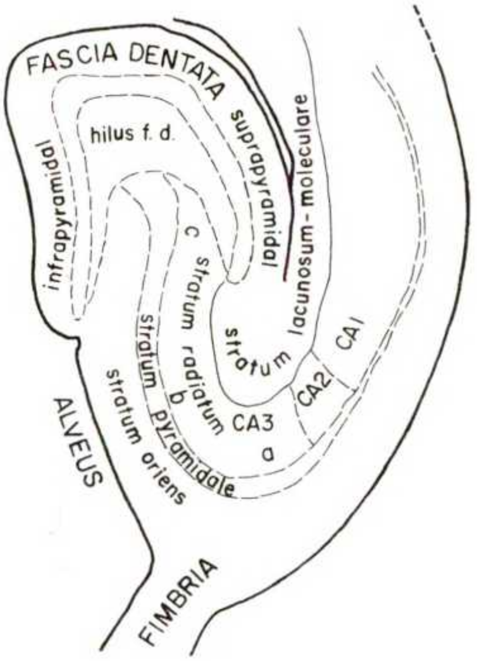

Fig. 1 Diagram of Ammon's horn in the horizontal plane to indicate nomenclature. Regio inferior comprises CA3 and CA2; Regio superior, CA1. Although it is unclear whether CA2 exists as a defined area and to what extent its pyramidal cells receive mossy fibre terminals[13,15], we have designated with this term the border zone between Regio inferior and Regio superior within which the suprapyramidal mossy fibre bundle terminates, in accordance with the terminology used by Chronister and White[15], Angevine[19] and Hine and Das[21].

mossy fibre bundle, extending as far as the border between Regio inferior (CA3–CA2) and Regio superior (CA1) (see terminology Fig. 1). Others take a more ventral, intra- and infrapyramidal route for a short distance, synapsing with excrescences of both the basal and apical dendrites of pyramidal cells in subfield CA3$_c$ before joining the suprapyramidal bundle (Fig. 2*a*)[13-15].

At most ventral and dorsal levels (not illustrated) some infrapyramidal mossy fibre terminals are also present in CA2 and CA3$_{a-b}$. It is known, however, that at the middle septotemporal level, as defined by Haug[11], the infrapyramidal zone in CA2 and CA3$_{a-b}$ contains few, if any, mossy fibre terminals (Fig. 2*a*). It is at this level of the hippocampus that we found the most clear-cut changes in the experimental animals. As shown in Fig. 2*b*, at this level in the hyperthyroid rat a dense layer of Timm reaction product, whose thickness is approximately one-third of the suprapyramidal mossy fibre layer, is consistently located in an infrapyramidal position in CA3$_{a-b}$, and CA2, reaching the border with CA1. Rows of Timm granules cross the pyramidal cell layer, suggesting that many infrapyramidal mossy fibres originate from the suprapyramidal bundle. A number of Golgi rapid sections available now supprt the former view, although it is also possible that some fibres originate from the infrapyramidal bundle. Also, preliminary electron microscopic studies show bundles of infrapyramidal mossy fibres in hyperthyroid rats with *en passant* mossy swellings synapsing on excrescences of the basal dendritic stems of pyramidal cells in CA3$_{a-b}$. In normal animals the basal dendrites of pyramidal calls receive little, if any, mossy fibre input in this field of Ammon's Horn, and have smooth shafts with few and simple spinous evaginations.

Why the lower border of the mossy fibre bundle is drastically changed and the transverse (between Regio inferior and Regio superior) and upper (towards the stratum radiatum) borders are not, may depend on the time at which the administered hormone starts to interfere with the morphogenetic process.

Various studies on hippocampal development [16-23] indicate that in addition to specific chemical affinities and recognition phenomena, temporal factors are of considerable morphogenetic importance. Complex spatio–temporal relationships between the time of origin and subsequent differentiation of granule cells and pyramidal cells have been demonstrated. These patterns include the start of granule cell differentiation in the suprapyramidal (lateral) blade of the dentate gyrus earlier than in the infrapyramidal (medial) blade and the birth of granule cells nearest the molecular layer before those towards the hilus[16,17] an 'inside-out' pattern of pyramidal cell generation[19,21] in that the deep pyramidal cells are born before those more superficial in the pyramidal layer, and the formation of apical pyramidal cell dendites earlier than basal dendrites[22]. Such spatio–temporal relationships between the differentiation of hippocampal granule cells and their pyramidal cell targets could provide an ideal system for the formation of discrete mossy fibre pyramidal cell connections, as suggested by recent studies in the mutant mouse[23].

How the position of individual mossy fibres within the suprapyramidal bundle is determined remains to be ascertained. In the cerebellum the parallel fibre growth is appositional, that is, the lower fibres are formed first and the most superficial last[24,25]. The existence of a chronological-positional order in

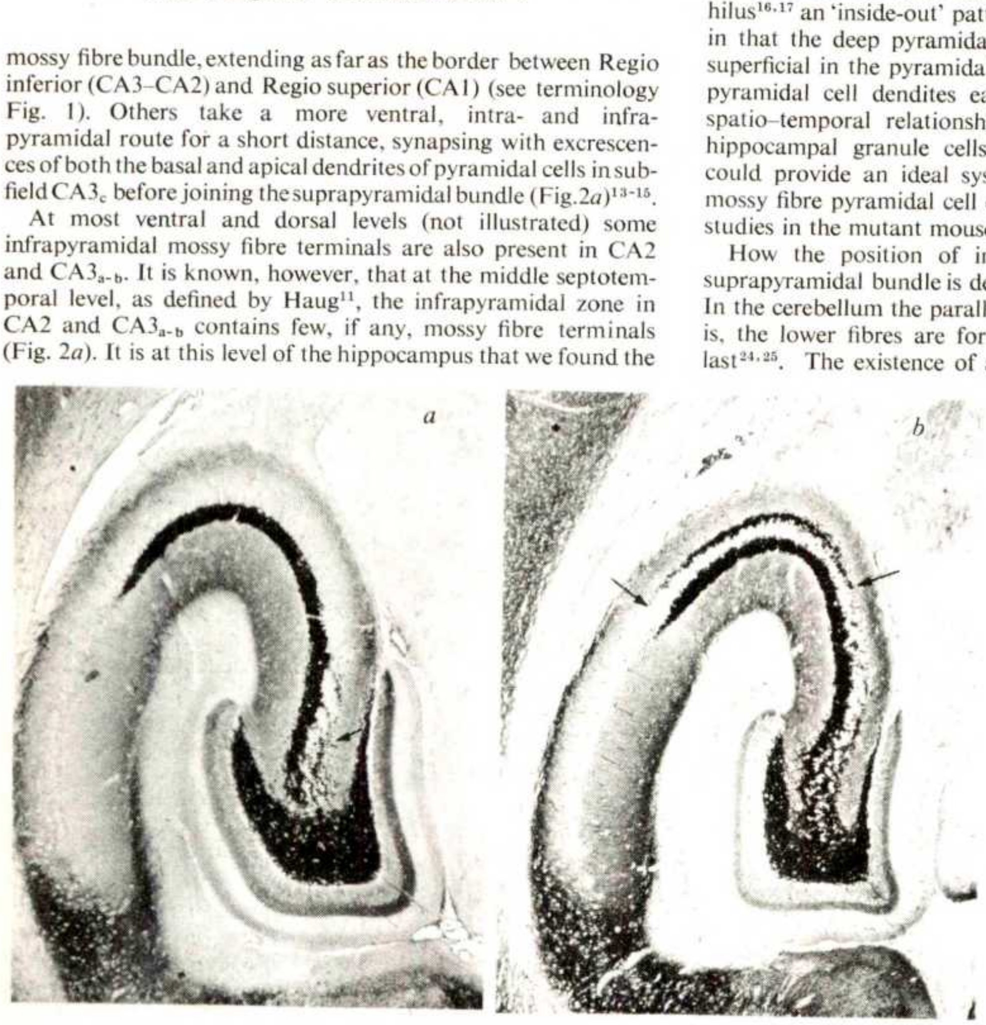

Fig. 2 *a*, Horizontal hippocampal section from saline-injected 30-d-old rat; Timm staining method; middle septotemporal level of the hippocampus as defined by Haug[11] (his Fig. 2*c*). The Timm precipitate marks the hilus fascia dentatae, the mossy fibre layer in CA3$_{abs}$ and that part of CA3$_c$ where mossy fibre bundles run through the pyramidal layer reaching an infrapyramidal position (arrow). In CA2 and especially CA3$_{a-b}$ the infrapyramidal zone shows only scattered Timm-positive granules (unlabelled). ×30.2 *b*, Horizontal hippocampal section from a 30-d-old rat injected daily with 10 µg L-thyroxine from birth to day 15. Middle septotemporal level of the hippocampus as defined by Haug[11]. Note the conspicuous Timm staining in the infrapyramidal zone of CA2 and CAC$_{a-b}$ (arrows). ×30.2

the hippocampal mossy fibre bundle is suggested by the fact that with postnatal hyperthyroidism the ectopic synapses are formed infra- and not suprapyramidally.

Other available data suggest that the abnormally expanded mossy fibre area in the hyperthyroid rat may be a consequence of an exaggerated growth of postnatally-generated granule cell axons and of an acceleration of granule cell differentiation. An effect of thyroid hormone on axonal growth has been indicated in recent developmental and regeneration studies[1,26]. Moreover, in the cerebellum, early hyperthyroidism accelerates the peak of postnatal granule cell differentiation[2]. This experimental condition also results in a permanent deficit in total cell number in the cerebrum and cerebellum[27], apparently caused mainly by early cessation of proliferation of germinal cells which results in a smaller number of postnatally generated microneurones. It would be interesting to know whether the number of hippocampal granule cells is also reduced. The effect of thyroid hormone on growth of the hippocampal mossy fibres could be more powerful than it seems from our work if the expanded mossy fibre area were produced by a smaller number of granule cells.

Although a primary effect on the presynaptic element seems probable, at present neither a direct influence of thyroid hormone on the pyramidal neurones, nor an indirect one by way of other hormones can be ruled out, especially since the dendritic tree of the pyramidal neurones is still undergoing development during the hormonal treatment. The aberrant mossy fibre terminals may occupy vacant postsynaptic sites, successfully compete for existent synaptic loci, or induce the formation of new ones. These questions and whether the ectopic mossy fibres are functionally active, remain to be determined.

Our results are somewhat germane to the demonstration of axonal 'sprouting' and 'expansion' of undamaged terminal areas after partial de-afferentation of various cortical and subcortical areas during development[28]. The hormonal treatment, however, affords the possibility of producing heterotopic synapses without the degeneration of neuronal elements and the glial cell proliferation which follows de-afferentation. The expanded target area of the mossy fibres in the hyperthyroid rat, represented by the accessory infrapyramidal bundle in CA2 and $\mathrm{CA3}_{\mathrm{a-b}}$, indicates that the normal pattern of axonal growth can be altered experimentally at a site where segregation of afferents appeared so strict as to be paradigmatic.

Generality of oestrogen stimulation of peroxidase activity in growth responsive tissues

OVER 20 years ago, Stotz *et al.*[1] reported that administration of oestrogen to rats effected an increase in the peroxidase (EC 1. 11. 1. 7) activity of the uterus. Subsequently, this stimulation of uterine peroxidase activity was attributed to an influx of eosinophils into the tissue[2]. More recent evidence, both biochemical[3–5] and histochemical[6–7], clearly indicates a uterine origin for the enzyme. On the basis of histochemical peroxidase assays, we proposed that peroxidase may be a useful marker protein response elicited by oestrogen in those rat tissues, like uterus[8], vagina[8] and mammary tumour[9], whose growth is regulated by oestrogen. Recent data[10] on the dose and steroid dependence of rat uterine peroxidase induction also supports this proposition. To be a meaningful marker for the effect of oestrogen on growth responsive tissues, the peroxidase induction should be demonstrable in animals other than the rat and should show a reasonable tissue specificity. This communication reports on the generality and specificity of oestrogen regulation of peroxidase activity.

Rats (Sprague–Dawley strain), mice (Swiss Albino strain), and hamsters (Golden Syrian strain) were obtained from ARS/Sprague–Dawley, Madison, Wisconsin. Guinea pigs (Hartley strain) were obtained from Camm Research, Wayne, NJ. Animals were injected with oestradiol-17β, (Sigma) 40 μg per kg body weight in 25% ethanol–saline or vehicle alone, 44 and 20 h before decapitation. Trimmed tissues were homogenised in cold 10 mM Tris-HCl, *p*H 7.2 buffer, 25–50 mg tissue per ml, centrifuged 45 min at 39,000*g* 2 °C and the peroxidase activity solubilised by rehomogenising the sediments with 0.5 M $CaCl_2$ in 10 mM Tris buffer, *p*H 7.2. The extracts were collected after 45 min, 39,000*g* centrifugation at 2 °C. Although both the hypotonic and $CaCl_2$ extracts were assayed for peroxidase activity, only minimal activity was found in the original 10 mM Tris supernatants (<5% of total).

Peroxidase assays were performed by modification of the method of Himmelhoch *et al.*[11], at 25 °C. The assay mixture, 3.0 ml total volume, contained 13 mM guaiacol and 0.3 mM H_2O_2 in 10 mM Tris buffer, *p*H 7.2 containing 0.5 M $CaCl_2$. The reaction was started by the addition of enzyme (extract) and initial rates of guaiacol oxidation were determined from the increase in absorbance at 470 nm for the first minute. An enzyme unit was defined as the amount of enzyme required to produce an increase of one absorbance unit per minute in these assay conditions.

Table 1 shows the effect of two injections of oestradiol on the uterine wet weight and uterine peroxidase activity in four species of laboratory animals. In each case, there was a significant increase in both uterine weight and uterine peroxidase content but it is apparent that there were appreciable differences in the uterine sensitivity of these various animals to oestrogen, given at identical doses based on body weight. However, the relative increases in peroxidase content closely parallel the relative increases in weight of the uteri. Thus, the hamster showed the smallest increase in uterine weight (35%) and the smallest

Table 1 Oestradiol stimulation of the uterus of various species

Animal (age/wt)	Group*	Uterine wt (mg)	Uterine peroxidase activity Units (per g ± s.e.m.)	Uterine peroxidase activity mUnits per uterus
Hamster	C	45.8	0.064±0.018	2.9
(25 d/46 g)	E	62.4	0.132±0.016	8.2
	(E/C)	(1.36)	(2.06)	(2.9)
Guinea pig	C	232	0.18±0.04	42
(23 d/210 g)	E	534	0.83±0.17	443
	(E/C)	(2.30)	(4.61)	(10.5)

	(E/C)	(4.49)	(293)	(1,315)

*Animals (4–10 per group) received subcutaneous injections of vehicle(C) or oestradiol (E) 40 μg kg^{-1} body weight, 44 and 20 h before killing. E/C is ratio of weight or peroxidase of oestrogen treated to control uteri.

increase in uterine peroxidase (2-fold). The most dramatic uterine sensitivity to oestradiol was seen in the mouse in which the uterus grew about 4.5-fold and showed almost a 300-fold increase in peroxidase concentration. The rat and mouse showed remarkable (300- and 1,300-fold) increases of total uterine content of peroxidase in 44 h of oestradiol treatment.

The oestrogen stimulation of peroxidase activity seems to be restricted to growth-responsive tissues (Table 2). Significant increases in peroxidase concentration are seen in both the uterus and vagina of the immature rat given oestradiol, but no peroxidase is found in the pituitary. Although small to large concentrations of peroxidase can be found in the kidney, thyroid, lung and spleen, no appreciable change in the peroxidase content of these tissues occurs on oestradiol treatment. Other tissues assayed, specifically ovary, adrenal and liver, had no significant peroxidase in the oestrogen-treated or untreated rat. Although the peroxidase content of the thyroid of the immature animal is low, the adult rat thyroid peroxidase content (about 40 units g^{-1}) was not influenced by oestrogen treatment.

Figure 1 shows the peroxidase content of some human oestrogen-responsive tissues. The endometrium and myometrium were obtained by physical separation from small samples of human uterus. While care was taken to obtain pure endometrium, it is probable that the myometrium contained some residual glandular tissue. Clearly, the peroxidase content of uterine endometrium exceeds that of the myometrium. Samples of human breast cancer tissue showed a wide range of peroxidase content. Nine of the 39 samples (23%) had no peroxidase, while 11 (28%) had an appreciable amount, that is greater than 1 unit g^{-1}.

Up to the present, there has not seemed to be any particularly meaningful protein marker for oestrogen action in the mammalian uterus. Although the induced protein or IP, first described by Gorski *et al.*[12] has generated considerable interest in this regard, a recent report[13] suggests that this protein may be limited to the rat uterus; it was not found in the uterus of the mouse, rabbit, hamster or guinea pig, or in the rat vagina. Whereas certain enzymes, especially those involved with carbohydrate metabolism, have been found to increase in the uterus of the oestrogen treated animal, the extent of these increases are generally small, at best 5–10-fold[14], and largely reflect the increased metabolic activity of the tissue.

Table 2 Tissue specificity of oestrogen effect on peroxidase activity

Rat tissue	Peroxidase activity (units per g) Control	Peroxidase activity (units per g) E2 treated*
Uterus	0.16	32.4
Vagina	0.0	5.8
Pituitary	0.0	0.0
Kidney	0.4	0.5
Thyroid	0.4	0.5
Lung	15.6	20.4
Spleen	186	188

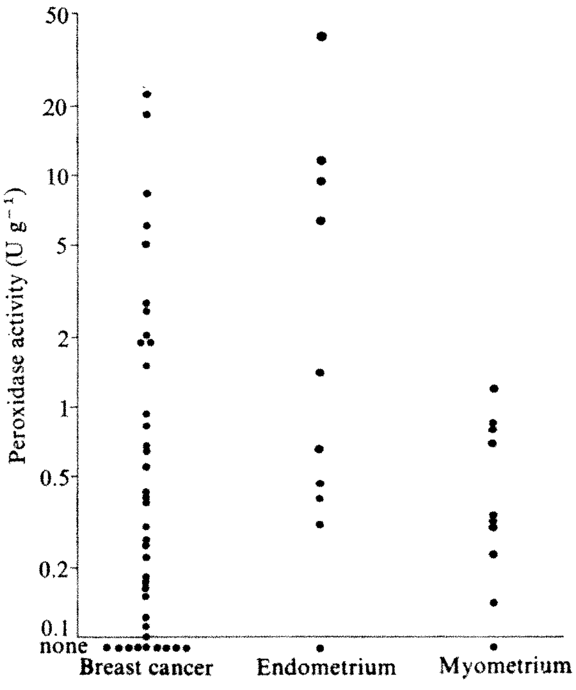
*Immature female rats given oestradiol-17β, 40 μg per kg body wt, subcutaneously 44 and 20 h before killing.

Uterine peroxidase activity seems to be a good marker for oestrogen stimulation of growth. As shown in this report, oestrogen effects a growth-related increase in peroxidase concentration in the uterus of various species. Furthermore, the oestradiol stimulation of the uterine peroxidase content of the immature mouse and rat uterus, as much as a 1,000-fold increase, is certainly one of the most dramatic effects of oestrogen. Peroxidase stimulation by oestrogen is limited to the growth-responsive normal tissues, uterus and vagina, and is not seen in the pituitary where the response to oestrogen is largely functional. Oestrogen-independent tissues of the rat show no significant stimulation of peroxidase content, whether or not the tissue of the untreated animal contained any enzyme.

An earlier report[15] indicated that the peroxidase content of human endometrial brushings showed a variation coinciding with the menstrual cycle. Since the human uterine samples reported here were from pre-menopausal patients, the range of peroxidase content probably reflects menstrual cycle variation. The high endometrial peroxidase concentrations agree quantitatively with the concentrations found in the oestrogen-stimulated rodent uterus (Fig. 1 and Table 1), suggesting that studies on the regulation of peroxidase in the rodent uterus are quite relevant to the human.

It is particularly interesting to find that a significant

Fig. 1 Peroxidase content of human uterus and breast cancer. Calcium chloride extracts of samples of human endometrium, myometrium and breast cancer tissue assayed for peroxidase content.



number of human breast cancer specimens contain appreciable amounts of peroxidase activity. An earlier report from our laboratory described the oestrogen regulation of peroxidase in the carcinogen-induced mammary tumours of the rat[9]. Data of the last 5 yr have indicated that essentially only those patients whose breast cancer tissue contains appreciable amounts of oestrogen receptor respond to endocrine therapies[16,17]. Since, however, at least a third of the patients with oestrogen receptor positive tumours do not respond, it is apparent that the presence of oestrogen receptor is an essential, but not necessarily sufficient, condition for response. It is possible that use of an assay of a biochemical parameter, possibly peroxidase, which reflects tissue hormone-dependence may enhance the accuracy of prediction of response in those breast cancer patients whose tumours contain oestrogen receptor. Such studies are in progress.

The generality and specificity of the oestrogen stimulation of peroxidase activity in tissues which are stimulated to grow by oestrogen recommends this marker as a meaningful parameter for the more detailed studies of steroid hormone regulation of gene function as related to growth. Further study of peroxidase content of normal and neoplastic human tissues can provide a better understanding of hormonal regulation of these tissues and possibly a more accurate diagnosis of oestrogen-dependent neoplasms.

Comparative drug sensitivities of culture forms of *Trypanosoma cruzi* and *Trypanosoma dionisii*

AT least 12 million people suffer from Chagas' disease in South America, but despite intensive efforts over the last 65 yr, no treatment effective against all stages of the disease has emerged[1]. *Trypanosoma cruzi* the causative agent of the disease, develops intracellularly in the tissues of the heart and alimentary tract. Such development, together with the absence of effective chemotherapy, means that drug testing for agents active against Chagas' disease is time-consuming, costly and hazardous[2]. Because of the danger of infection when working with *T. cruzi*, it has been suggested by Baker[3] that other species of the subgenus *Schizotrypanum* of the genus *Trypanosoma* could be used as models for studying this parasite. *T. dionisii*, isolated from the bat, *Pipistrellus pipistrellus*, by Baker and Thompson[4], seems to be a particularly suitable choice because of its apparent non-pathogenicity in man[3]. The experiments described here show that *T. dionisii* can replace *T. cruzi* in *in vitro* drug screens.

Table 1 Effects of drugs known to be active in animal screens on the culture epimastigotes of *T. dionisii* and *T. cruzi*

*Detailed chemical structures in ref. 1.
†Abnormal appearance.
‡Not determined.

T. dionisii (from J. R. Baker, Molteno Institute, University of Cambridge) and the Sonya strain of *T. cruzi*[5] were maintained in modified LIT medium[6] at 28 °C. This was supplemented with 10% (by volume) heat-inactivated new-born calf serum for *T. cruzi* and with the same concentration of heat-inactivated rabbit serum for *T. dionisii*. Four-day-old cultures of each organism were used to inoculate fresh medium containing drugs to an initial cell density of 10^6 organisms per ml. The effects of the drugs on growth were observed over a 72 h incubation period. The drugs used included representatives of each of the eight chemical structures so far tested clinically against *T. cruzi*[1]. The results (Table 1) showed that the drug sensitivities of the two species are almost identical. This suggests that *T. dionisii* can be used to replace *T. cruzi* in drug screens of this kind. Primary *in vitro* drug screens, however, are never entirely satisfactory since some false-positive and, more significantly, a few false-negative results will appear[7]. The absence of activity with Bayer 7602 Ac, which is quite active in animal screens and the detection of activity with cordycepin, which is relatively inactive *in vivo*, indicates that *T. dionisii in vitro* is not an exception to these limitations. But, if the alternative is no routine testing at all, as seems to be the situation now[1], we suggest that the use of *T. dionisii in vitro* as a safe, quick and inexpensive primary screen for detecting activity against Chagas' disease should be considered.

Eosinophils and not lymphoid K cells kill *Trypanosoma cruzi* epimastigotes

CHAGAS' disease caused by the protozoan *Trypanosoma cruzi* remains a medical problem of immense proportions in Latin America, and yet the study of the pathogenesis and immunology of the disease can reasonably be said to be in its infancy. The demonstration of the protective role of humoral immunity *in vivo*[1] and of antibody-dependent cell-mediated cytotoxicity against *T. dionisii in vitro*[2] has raised the question that this phenomenon may be important biologically in Chagas' disease and might be mediated by K cells normally assayed as killer cells against antibody-coated tumour cells[3]. Here we address the second part of the question, and show that K cells in rat spleen have no detectable activity against *T. cruzi*, but that the activity resides in cell preparations rich in eosinophils.

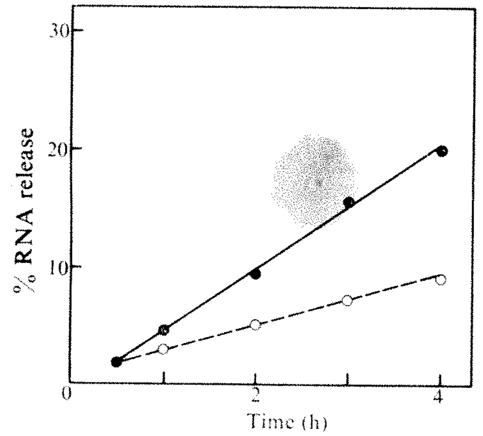

Fig. 1 Showing the time course of cytotoxicity of normal rat spleen cells in the presence (●) and absence (○) of antibody. An inbred line of white rats (O strain) was used. The antiserum was prepared by injecting rats with 10^6 blood forms from parasitaemic mice, and bleeding at 14 d. Culture forms of *T. cruzi* (Y strain) were inoculated into 1 ml of Warren's medium[9] containing 10 μCi of ^{3}H-uridine (43 Ci mmol^{-1}). After 5 d, the parasites were washed four times with medium (RPMI:1640 containing 10 mM HEPES and 5% inactivated foetal calf serum), resuspended to a concentration of 10^6 ml^{-1} and distributed (100 μl) in small plastic tubes. Spleen cells were added in a volume of 100 μl to give a ratio of 20:1 (cells:parasites). The antiserum diluted 1:100 was added as a further 100 μl (total volume 300 μl). The tubes were incubated at 37 °C, and at the times indicated, tubes were removed from the incubator, resuspended and centrifuged. After centrifugation, 200 μl of the supernatant was carefully removed to a counting vial. Total isotope in 10^5 parasites was determined by placing 100 μl of the original parasite suspension in a counting vial. The parasites were lysed by adding 100 μl of 1% Triton X-100. A 2-ml aliquot of a water-miscible scintillation fluid (1 vol. Triton X-100 and 2 vol. toluene-based scintillation fluid) was then added to each vial. The vials were counted in a liquid scintillation counter, and after correcting for background, % RNA release was calculated: $1.5C \times 100/T$ (T = the total counts in 10^5 parasites (mean of 4 replicates) and C = counts in each test vial (2/3 of supernatant counts)). The results were analysed by analysis of variance using logarithmic transformation, and Duncan's multiple range test[10]. All points shown are significantly different at the 5% level or less. Control release in the presence of antibody but absence of cells was not significantly different from (○), and has not been plotted.

It has been necessary to develop a simple and economical isotopic technique to assay parasite death. It has been noted previously (and we have confirmed it) that trypanosomes do not incorporate sufficient ^{51}Cr to provide a cytotoxic assay[2]. Those authors described a technique using ^{99m}Tc, but the limited availability and short half life (6 h) of this isotope provide considerable practical difficulties. Based on experiments with tumour cells where the release of RNA was found to provide a sensitive assay for cytotoxicity[4], we investigated the use of ^{3}H-uridine to label the RNA in the parasite. We have found (to be published) that, as is the case with tumour cells, RNA is released more rapidly than DNA and more completely than protein from killed parasites. Culture forms (largely epimastigotes) were labelled by growing them in a medium containing ^{3}H-uridine and >95% of the incorporated label was precipitable by 5% trichloracetic acid (and thus RNA). Figure 1 shows the release of RNA from *T. cruzi* by normal rat spleen cells in the presence and absence of specific antibody to the parasite, in medium containing inactivated foetal calf serum.

To investigate the properties of the cells mediating this cytotoxic reaction, the spleen cells were fractionated by Ficoll–Hypaque into high and low density fractions[5], followed by nylon wool columns to separate the cells on the basis of their adherence properties[6]. These fractions were tested against antibody-coated P815 cells as an assay for K cells, and against antibody-coated *T. cruzi*. It has already been shown that K cells are low density, non-adherent cells[4,7].

The activity against *T. cruzi* (Fig. 2) is found in the high density fraction (*P*) which contains very little activity against the

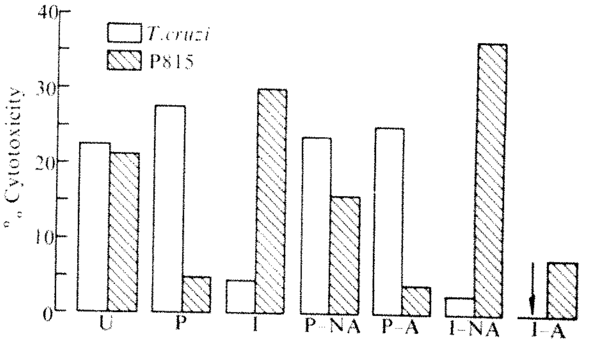

Fig. 2 Comparison of cell fractions against P815 mastocytoma cells using a ^{51}Cr release assay[4] and *T. cruzi* using the RNA release assay described in Fig. 1. Each fraction was tested in the presence and absence of the specific antibody for the appropriate target. U, Unfractionated rat spleen; P, pellet; I, interface after Ficoll–Hypaque separation[5]; P–NA, pellet cells after passage through nylon wool (non-adherent); P–A, pellet cells recovered from the nylon wool column (adherent cells); I–NA, interface cells non-adherent to nylon wool; I–A, interface cells adherent to and recovered from nylon wool. Nylon wool was used as described previously[6,7]. Assay against *T. cruzi* was carried out at a ratio of 20:1 for 4 h and against P815 was carried out at a ratio of 40:1 for 3 h after light centrifugation. % cytotoxicity was calculated from % isotope release: (test − control)/(maximum − control), where test = % release in the presence of antibody, control = % release in the absence of antibody, maximum = release after freezing and thawing (100% for RNA from *T. cruzi* and 81% for ^{51}Cr release from P815). The control values were 12.0% for *T. cruzi* and 15.5% from P815. None of the control values was more than 3% higher than the spontaneous release (tubes containing antibody but not effector cells). The arrow indicates a value where the difference between the presence and absence of antibody was not significant at the 5% level.

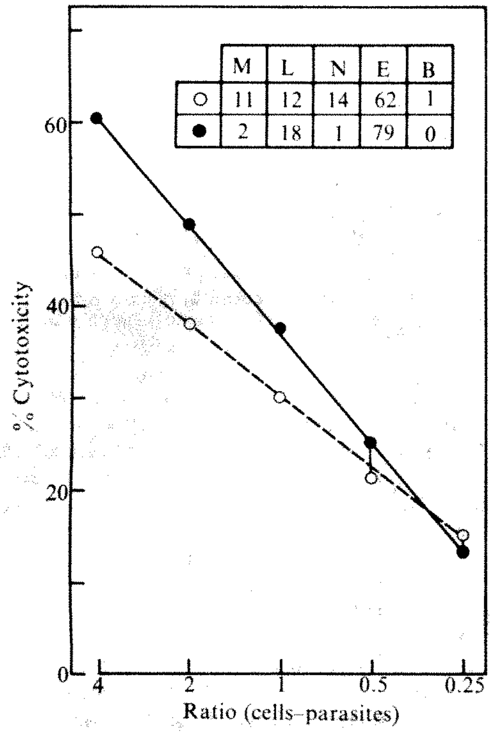

Fig. 3 An experiment using cells induced with dextran (molecular weight 70,000) and rich in eosinophils. Rats were injected with 5 ml of 6% dextran 15 h before collection of the exudate. The cells were tested unfractionated (○) and after carbonyl iron treatment (●) to remove adherent cells, by incubating 5 ml of cell suspension with 50 mg of carbonyl iron for 15 min at 37 °C. The non-adherent cells were recovered using a magnet. Differential cell counts were made after staining with May–Grunwald–Giemsa, and the values are the mean counts made by three different individuals. M, macrophages; L, lymphoid cells; N, neutrophils; E, eosinophils; B, mast cells. The two lines are significantly different at the 1% level, although the individual points joined by a vertical line are not significantly different at the 5% level. Linear regression analysis; (○) slope 5.96+0.36, correlation coefficient 0.986; (●) slope 8.99+0.29, correlation coefficient 0.996.

tumour cells. On the other hand, very little activity against *T. cruzi* is found in the low density fraction (*I*), which contains most of the activity against the tumour cells. The two activities are virtually mutually exclusive, as can be seen by comparing the activities in the pellet (P) with the interface cells (I) or the interface non-adherent cells (I–NA). This indicates that K cells have insignificant activity against *T. cruzi*, and that the cells active against the parasite have insignificant activity against these tumour cells. The high density of the active cells suggested that they may be granulocytes. To investigate this possibility, we induced peritoneal exudates with high proportions of granulocytes and tested them as effector cells against antibody-coated *T. cruzi*. Preliminary experiments with exudates rich in neutrophils or eosinophils suggested that eosinophils were the effector cells, and this can be seen in Fig. 3 where unfractionated exudate cells with 62% eosinophils shows spectacular activity against *T. cruzi* (a ratio of 1:1, giving 30% cytotoxicity in 4 h). Treatment of this exudate with carbonyl iron and a magnet to remove macrophages and neutrophils resulted in an increase in the activity against *T. cruzi* (a ratio of 1:1 giving 37.5% cytotoxicity). These types of experiments show that eosinophils can kill *T. cruzi*, but do not completely exclude other cell types from a subsidiary role.

In summary we have described an isotopic technique for assaying the killing of *T. cruzi* epimastigotes in which the criterion of parasite death is the release of macromolecular RNA. Apart from the obvious advantage that the assay measures the release of one of the parasites' natural macromolecules, and so can be taken as a good indicator of lysis, the fact that RNA is almost totally released when the parasites are lysed makes the assay sensitive. We have used the assay to investigate the nature of the effector cell killing *T. cruzi* in an antibody-dependent, complement-independent system. Eosinophils show strong activity, whereas lymphoid K cells seem to have insignificant activity.

Whether this eosinophil-mediated killing plays any biological part in the pathogenesis of American trypanosomiasis remains to be tested, but like experiments with *Schistosoma mansoni*[8], the present report adds another biological activity to our knowledge of the eosinophil.

This work was supported by grants from the Brazilian National Research Council (CNPq), and the National Fund for Research in Brazil (FINEP). CJS was supported in part by a visiting professorship from the Federal University of Rio de Janeiro. We thank Dr G. M. Oliveira Castro for his support and advice.

Note added in proof: We have been unable to induce eosinophil exudates with dextran in other strains of rats.

Type C virus expression and host response in diet-cured NZB/W mice

THE immune complex renal disease of NZB/W mice is largely prevented and survival of the animals markedly prolonged by protein or calorie restriction[1,2]. These same dietary restrictions depress the antibody response[3-7] and inhibit the development of spontaneous cancer[8-10] in experimental animals. Spontaneous release of endogenous type C viruses (MuLV) and the autogenous host humoral immune response to these MuLV have been implicated in the aetiology of autoimmune disease in NZB and (NZB×NZW)F_1 (B/W) mice[11-14]. We wondered whether the disease-sparing effect of a low protein diet in B/W mice was attributable to a decrease in the production of endogenous MuLV or a reduction in the host response to this virus. Our findings suggest that neither of these events is responsible for the disease prevention.

Female B/W mice, raised in our laboratory breeding colony[15], were maintained from 4 weeks of age on a low phenylalanine-low tyrosine diet. This diet prolongs survival and prevents immune complex nephropathy in B/W mice[1]. Control mice were fed an unrestricted *ad lib* diet. Mice were necropsied when sick or at termination of the experiment and tissues were studied by light microscopy. The low phenylalanine-low tyrosine diet led to a significant prolongation of life (Fig. 1). The median survival on this restricted diet was more than doubled, that is, 24.3 months compared to 9.7 months for mice on the *ad lib* diet, and the relative death rate[16] was nearly fivefold less than in the *ad lib* diet group ($P < 0.001$). Of 23 mice in the restricted diet group, 15 were killed while still healthy at 2 yr

Table 1 Type C virus recovery from tissues cultivated from female B/W mice on amino acid restricted and *ad lib* diets

	Virus isolations			
Diet	Xenotropic	General titre (FFU ml^{-1})	Ecotropic	General titre (PFU ml^{-1})
Low amino acid	3/3	1,000	1/3	10,000
Ad lib	5/5	1,000	2/5	10,000

Values represent the number of mice which yielded virus/number tested. Assay for X-tropic virus in B/W mice was performed by initially co-cultivating mouse tissues with nonvirus producing murine sarcoma virus (MSV) transformed rat cells. Spleen, thymus and kidney tissues were co-cultivated from each mouse. After 7 d, the supernatant of these cultures was filtered and assayed for focus forming virus on rat or human cells[17,18]. Titre is expressed as focus forming units (FFU) per ml and is the general titre observed with cultures of the individual organs. The quantity of X-tropic virus produced by the mouse cells correlated with the amount of pseudotype MSV produced by co-cultivation[27]. Ecotropic virus produced by the mouse tissues was assayed by the standard XC plaque technique[28]. The titre is expressed as plaque forming units (PFU) per ml.

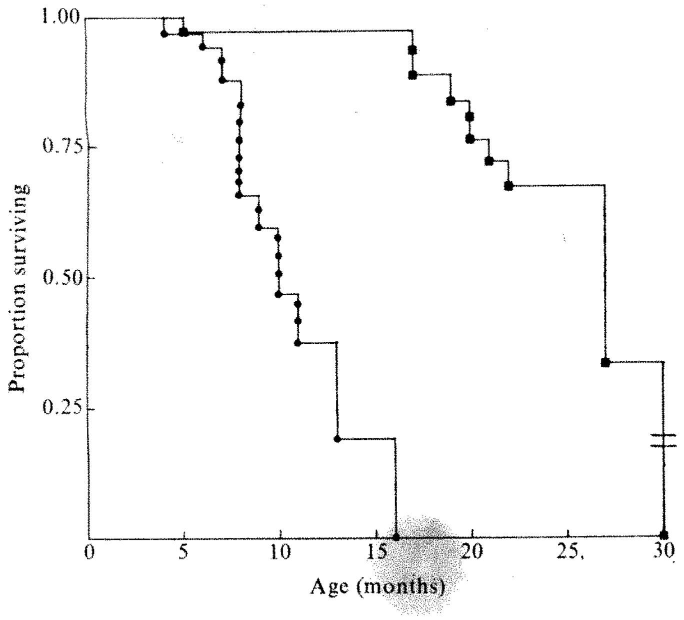

Fig. 1 Survival curves of B/W female mice on amino acid restricted (■) and *ad lib* (●) diets. The amino acid restricted group contained 35 mice and the *ad lib* diet group 32 mice. The data include killed and dead mice under long term observation as well as those sacrificed at 8 months of age. The survival curves and relative death rates were calculated using the actuarial life table approach and observed numbers of death in each group were compared to their expected numbers, assuming that no difference existed between groups[16].

of age and minimal glomerulonephritis was observed in only 3. Of the 8 mice in this diet group that were found dead between 5 and 30 months of age, 3 showed moderate glomerulonephritis and the other 5 died of unrelated causes. Thus, about 75% (17 of 23) of the diet-restricted mice were free of renal disease at an average age of 20 months. In the *ad lib* group, by contrast, all (29 of 29) mice had severe glomerulonephritis at an average age of 8 months. In general, the glomeruli in the diet-restricted group were neither enlarged nor hypercellular and there was no thickening of the mesangial matrix or capillary basement membranes. Immunoperoxidase staining also demonstrated a marked decrease of immunoglobulin deposition in the kidneys of the restricted diet mice compared to the control mice (data not shown). We thus confirmed that diet-restriction has a profound inhibitory effect on the development of immune complex (IC) nephritis in B/W female mice ($P < 0.001$). A similar preventive effect upon malignancy was not noted since lymphomas were found in two of the amino-acid restricted B/W mice at 21 and 24 months of age, whereas no lymphomas were found in the shorter lived B/W mice on the *ad lib* diet.

To determine whether the diet had any influence on production of endogenous type C virus we assayed tissues of amino acid-restricted B/W females aged 19–23 months and compared their virus expression with that of B/W controls on an *ad lib* diet. It has been shown that all cells from NZB and B/W mice produce in substantial titres an endogenous xenotropic (X-tropic) virus that can productively infect only cells from a heterologous species[13,14,17,18]. Tissues from the B/W hybrid sometimes also produce an endogenous ecotropic virus, present in the NZW parent, which infects and spreads readily in mouse cells[13]. As shown in Table 1, the prevalence and titre of X-tropic virus released by different tissues of the amino acid-restricted B/W mice were equivalent to those of control B/W mice. It is apparent that the dietary prevention of IC nephritis in B/W mice was not linked to any decrease in the production of endogenous X-tropic virus as measured by our *in vitro* technique. Moreover, since these diet-restricted mice had almost no signs of IC nephritis 1–11 months after the virus titre in their littermates was assessed, high production of X-tropic virus did not correlate with ultimate development of kidney lesions. In two controls and one experimental mouse, ecotropic AKR-MuLV was also detected. The presence of this virus was not associated with any specific pathological changes in the kidney.

We next determined whether the prevention of IC nephritis by the restricted diet correlated with any reduction in the host

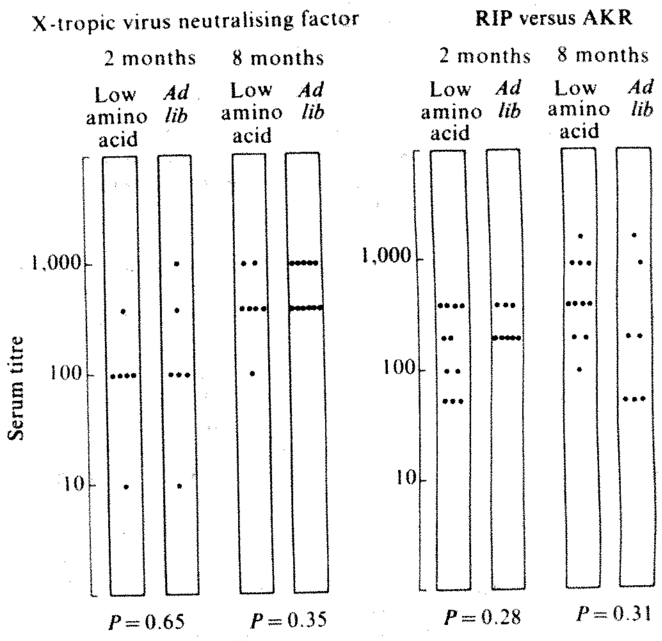

Fig. 2 Levels of anti-viral activity in female B/W mice fed amino acid restricted and *ad lib* diets. Sera were diluted 1:5 in phosphate buffered saline. Neutralisation activity was measured by reduction of foci on NRK cells of an NZB pseudotype sarcoma virus bearing the X-tropic virus type specific envelope antigen, as described[18,23]. The radioimmune precipitation assay of intact labelled ecotropic (AKR) virus has also been described[20]. At 8 months of age severe glomerulonephritis was present in all controls but was totally absent in those mice fed the restricted diet.

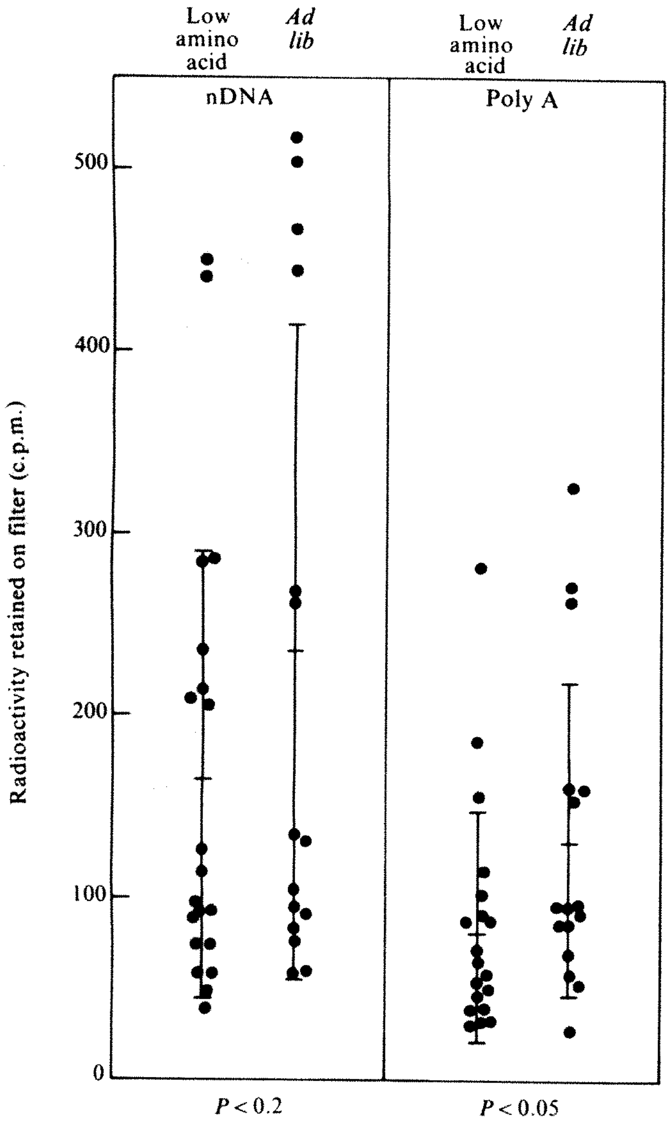

Fig. 3 Serum anti-nucleic acid antibodies in 8 month old female B/W white mice fed amino acid restricted and *ad lib* diets. Antibodies to native DNA (nDNA) and polyribonucleic acid (poly A), a single stranded RNA, were determined by a cellulose ester filter radioimmunoassay[29]. 100 μl of a 1:10 dilution of serum in minimum essential medium was heat inactivated at 56 °C. After adding 10 μl of ^{3}H-DNA (116 ng, 800 c.p.m.) or ^{3}H-poly A (7 ng, 800 c.p.m.), the reaction mixtures were incubated at 37 °C followed by incubation for 18 h at 0 °C. The reaction mixtures were diluted and passed through Millipore filters. The filters were washed, dried, and the radioactivity retained on the filters was counted by liquid scintillation.

response to endogenous viruses. A breakdown in the control of endogenous type C viruses could lead to high tissue and serum concentration of these viruses and the resultant hyperresponse to one or more of the viral antigens, for example, envelope glycoproteins (gp70), might contribute to the renal glomerular immune complex deposition[11,19]. Binding antibodies to intact labelled AKR ecotropic virus have been found in the sera of B/W mice[20] but no antibodies to X-tropic virus have been detected[21]. But, a serum non-immunoglobulin factor associated with mouse lipoproteins has been identified which neutralises specifically this X-tropic class of endogenous MuLV (refs 22, 23). No significant differences were found in the titre of either X-tropic virus neutralising factor or antibodies to the AKR-MuLV in sera from the mice in amino acid-restricted or *ad lib* diet groups (Fig. 2). In both diet groups the X-tropic virus neutralisation titres increased somewhat with age. A similar age increase in the AKR precipitating antibody titre was noted in the amino acid restricted but not in the *ad lib* group. In general, the geometric mean titres (g.m.t.) and the titre range of both X-tropic virus neutralising factor (g.m.t. 500, range 100–1,000) and anti-ecotropic virus antibody (g.m.t. 320, range 100–1,600) were similar in both diet groups at 8 months of age to those values previously detected in untreated NZB and B/W mice[14,20,24]. Although subtle differences might yet be revealed if these analyses were done on a larger number of mice, these findings do suggest that the diet-induced prevention of immune complex nephritis in B/W mice is not due to any major decrease in production of X-tropic virus neutralising factor or precipitating antibodies to the endogenous ecotropic virus.

Another characteristic of the autoimmune disease complex in B/W mice is antibodies to nucleic acids. We found the mean binding of serum antibodies to native DNA and poly A was somewhat lower at 8 months of age in the group fed the amino acid-restricted diet compared to the control group (Fig. 3); this reached statistical significance ($P < 0.05$) only to poly A.

These data suggest that the dietary-induced increase in longevity and prevention of immune complex disease in female B/W mice is unrelated to any influence upon production of endogenous type C viruses or the autogenous host response to these viruses. A similar lack of association between autoimmune markers and high titres of xenotropic virus was found in F_1 progeny of crosses between NZB mice and other strains of laboratory mice[25]. If one assumes that virus production *in vivo* is accurately represented by the *in vitro* virus assays, these observations suggest that the IC renal disease in B/W mice is not solely a consequence of spontaneous oncornavirus production. The trend towards reduction in antibodies to nucleic acids observed in the diet-treated mice, although not profound, may have contributed to the reduction in IC nephritis since about half of the immunoglobulin deposited in glomeruli of control B/W mice reacts with nucleoprotein[26]. Measurement of the total immunoglobulin levels, the types of immunoglobulins produced, and the quantitation of circulating immune complexes might clarify further whether the diet-induced disease-protection involves a generalised decrease in antibody synthesis. The diet may decrease certain species of immunoglobulins or complexes other than those containing viral or nuclear antigens. These studies suggest, however, that since the diet did not significantly affect the host response to endogenous viruses or nucleic acids, other factors such as hormone levels and the number and function of cells responsible for mediating the immunological reactions may have been affected.

We thank Drs Robert Huebner and Frank Dixon for critical review, Ms Patricia Kazan and Mr John Estes for technical assistance, Dr Clive Taylor and Mr Robert Rongey for immunoperoxidase studies and Dr Malcolm Pike and Mr John Casagrande for statistical analyses. Epizootiology, transmission and approach to prevention of fatal simian haemorrhagic fever in rhesus monkeys

RHESUS monkeys (*Macaca mulatta*) and all other macaques are extremely susceptible to the fatal disease, simian haemorrhagic fever (SHF). Introduction of this agent into a laboratory colony will result rapidly in the complete loss of all macaques in that colony[1-6]. An outbreak in one of our rhesus colonies resulted in the loss of all 212 animals in a period of 12 d. Because of this great loss and its consequences, we initiated an investigation into the epizootiology, transmission and prevention of this disease. These studies have shown that the virus is carried as a chronic infection in patas monkeys (*Erythrocebus patas*) with no apparent signs of disease. It can be transmitted to the rhesus monkeys by accidental inoculation with tissue fluids, and once they are infected, spread by aerosol and contact is rapid.

Clinically, SHF is a febrile, haemorrhagic disease of macaques caused by an RNA virus which has been reported to be a togavirus[5]. The disease is characterised by rapid onset, early fever, mild facial oedema, failure to eat or drink, dehydration, protein in the urine, cyanosis, haemorrhages of the skin, bloody diarrhoea, nosebleeds, occasional bleeding in the orbit of the eye and subsequent death in most cases. Pathological changes associated with the disease include widespread small to large skin haemorrhages, haemorrhagic tissue death of the first few centimetres of the small intestine, enlarged spleen, intravascular coagulation and generalised destruction of lymphoid tissue[3,7].

The epizootiology of SHF has been described for eight outbreaks[1,2,6]. The disease has only been observed in macaques. The first seven outbreaks involved recently imported rhesus monkeys with subsequent spread of the disease to other macaque species. The source of the eighth outbreak was not identified. All of the epizootics were characterised by an explosive onset, rapid spread within exposed groups and a high case–fatality ratio. No human illness was associated with either the current outbreak or previously reported epizootics of SHF.

In November and December 1972, an outbreak of SHF occurred in our colony in a building housing two groups of monkeys: 212 rhesus monkeys and 46 patas monkeys. The two groups were kept in separate rooms connected by an open loft : no other animals were housed in the building. Only the rhesus monkeys were involved and of the 212 animals, 172 had been in the colony for 6 months to 1 yr. The other 40 rhesus monkeys were introduced into the colony in a one-week period. The new animals had been conditioned for 60 d at the facilities of an animal importer, during which they were held in two separate rooms with no other animals. The patas monkeys had been in our colony for 2 yr.

Except for diarrhoeal disease in 10 of the newly arrived rhesus monkeys, no major disease problems were noted in the colony until about 30 d after the last animal was introduced. Suddenly, within one day, 60 rhesus monkeys, including all 40 newly arrived animals, developed a clinical illness characterised by depression and loss of appetite. The following day, an increasing number developed a similar illness. Many of the animals observed to be ill the previous day had developed facial cyanosis and showed dilated pupils; 15 of the animals were too weak to stand. The first fatalities occurred 3 d after the onset of illness, when 10 animals were found dead. Within 4 d, all remaining rhesus monkeys were affected clinically, and nine additional monkeys had died. In 12 d, a total of 106 monkeys had died. At this time, all surviving macaques were in advanced stages of illness and so were killed. At necropsy the affected animals had lesions characteristic of SHF. At no time did the patas monkeys exhibit signs of disease.

The disease seemed to have spread within the rhesus colony by direct and indirect contact exposure. Although all monkeys in the colony were in individual cages separated by a solid metal partition, they could touch each other by reaching around the partition. Also, all the female rhesus monkeys were weighed twice weekly as part of a nutritional experiment. For this, the animals were placed in one of three portable cages for transport to the scale. The portable cages were washed and autoclaved at the end of each day. Indirect contact of the monkeys did, however, result during use of these transfer cages for several animals on a given day. On some occasions, the same cages were also used to transport the patas monkeys to the scale.

Although spread by means of needles used in the treatment and tattooing of monkeys had been incriminated in previous epizootics of SHF, exposure by this route in this outbreak was investigated carefully and found to be limited to a small number of animals. The 40 newly arrived rhesus monkeys were tattooed using the same equipment on or shortly after arrival. The tattoo needle was cleaned with alcohol between animals. A few animals in the newly arrived group may have been given injections of vitamins and antibiotics with a common needle. Most of the infected animals, however, had not been tattooed or inoculated for a number of months before the outbreak.

In this outbreak, approximately 90 d (60 d at importer's and 30 d in our facility) had elapsed between importation of the newly introduced group of monkeys and the onset of the epizootic. Disease compatible with SHF had not been noted since 1965 at the animal importer's facilities and the importer had not heard of any similar disease problem in monkeys sold to other customers. In experimental studies the incubation period of SHF has ranged from 3–7 d after inoculation, with most deaths occurring within 7–13 d (refs 2 and 7). The short incubation period of the disease, the long time which elapsed between importation of the newly introduced monkeys and the onset of the epizootic, and absence of the disease in animals at the importer's facilities suggest that the rhesus monkeys were first exposed to the disease at the NIH colony. Studies on the transmission of the SHF were initiated and demonstrated that the disease could be spread from infected to uninfected rhesus monkeys by direct contact with animals in the same cage or by aerosol to animals in adjacent cages, as well as by inoculation. With inoculation, the animals died in 7–12 d.

In view of the extreme susceptibility and lethality of SHF in rhesus monkeys it is likely that this is not a natural epizootic disease of macaques. Once introduced into macaques either in the wild or laboratory colony, the disease would destroy essentially all animals in two weeks. The few remaining animals seen in laboratory conditions following a long period of supportive treatment are not chronic carriers of the virus, but have high levels of antibodies[4].

The investigation of the possible source and method of introduction of the infection into our rhesus population was fortunately made easier because only one other species of sub-human primate was in the building. For this reason, careful study of the patas monkeys was also initiated to determine if they were the source of the infection. Tests showed that when serum from some patas was inoculated intravenously into a rhesus monkey, SHF and death resulted in 4 d. In a subsequent series of studies, it was found that approximately 10% of recently imported patas monkeys were chronic carriers of SHF. Minute quantities of blood or tissue fluids could transmit the infection to the rhesus. Transmission did not occur between patas and rhesus when the animals were housed together in the same cages, so it obviously required direct mechanical transmission of infected tissues and did not occur by contact or aerosol. It seems that our epizootic was initiated by the use of a multidose vial which was used to inoculate animals of both species. The inappropriate re-introduction of a contaminated needle from animals with more than 10^{-12} ID (infective doses) per ml of blood into the vial following the injection of a chronically infected patas would have been sufficient to contaminate the vial contents and spread the disease to rhesus monkeys which were subsequently infected with material from the same vial.

Prevention of SHF can be accomplished by interrupting transmission from the natural reservoirs of infection. Transmission of SHF on this occasion occurred because asymptomatic patas monkeys, which chronically carry this virus, were maintained in the same building by the same personnel as rhesus monkeys and, unfortunately, because of a technical error, some of the contaminated tissue fluids from such a patas monkey was inoculated into a rhesus. Once the rhesus animal was infected, the disease spread through the rhesus colony by direct contact and aerosol. Thus, prevention of SHF in such colonies must include meticulous attention to prevent procedures which might transmit infected tissues from patas to rhesus. Whenever possible, the two species should be housed in separate facilities to minimise further the risk of cross inoculation.

Patas animals can carry this deadly virus for at least 2 yr, and we have also found that approximately 1% of baboons (*Papio papio*) and African green monkeys (*Cercopithecus aethiops*) we have studied carried latent SHF. To date, there has been no evidence that chimpanzees carry this virus. All other African species, however, should be considered possible carriers. Importations and shipments of monkeys must also be arranged to separate the African species from macaques since inadvertent exposure to blood or tissue fluid might occur in open wounds during shipment. Since SHF is a togavirus, the possibility of arthropod-borne transmission must also be investigated.

We have also reported that the complex of polyriboinosinic–polyribocytidylic acid-containing poly-L-lysine and carboxymethylcellulose is effective in preventing the spread of SHF in colonies of macaques if used in recently exposed animals[8]. Animals showing signs of disease however, were not helped by using this drug.

Y-forms as possible intermediates in the replication of measles virus nucleocapsids

THE genome of measles virus, a paramyxovirus, is a non-segmented single stranded RNA molecule which is enclosed within a helix of protein subunits to form a linear nucleocapsid[1]. Little is known about its mode of replication. It is known, however, for other paramyxoviruses that during the growth cycle transcription of the RNA occurs from an intact nucleocapsid by a virion-associated enzyme[2–4]. The resulting messenger RNA molecules are less than the full genome length and are unencapsidated[5]. By contrast, during viral RNA replication no free genome length RNA can be detected[5,6] and both plus and minus-stranded RNA are found only in the encapsidated form[7]. From this evidence, Kingsbury has suggested[7] that nucleocapsids of paramyxoviruses replicate without separation of the protein and nucleic acid portions of the template nucleocapsid and has implied that plus and minus-stranded RNAs enclosed within the capsid structure act as templates for each other. If this is so, association of the two types of nucleocapsid in a replicative form should be detectable in infected cells. We have conducted a search by electron microscopy for such structures in measles virus infected cells and the results are described here.

Vero cell monolayer cultures were infected with the P9 strain of measles virus[8] at a multiplicity of 1 pfu cell^{-1}. Preparations of nucleocapsid material for electron microscopy were obtained by lysis of the monolayers with a few drops of 2% phosphotungstic acid at 18–24 h post-infection, the time of maximum nucleocapsid synthesis. A small drop of the lysate was applied to a carbon-Formvar coated grid, blotted dry with filter paper and viewed in the electron microscope. Nucleocapsid lengths were measured on tracings of enlarged electron micrograph negatives or by counting capsid helix turns.

The majority of nucleocapsids observed were linear molecules. However, rare Y-shaped structures with two arms of equal and variable length were also observed (Fig. 1). Such structures would be expected for a replication mode in which one strand was being copied from one end. The variable lengths of the arms indicate that the structures represent different stages of replication.

From a large number of experiments, 26 structures were selected which we considered to be unambiguous Y-forms. In those with very short arms (Fig. 1*a*, *b*), the number of turns of the capsid helix was the same, ±1, for both arms. In those with longer arms, the lengths differed only by an amount probably consistent with the deformations introduced during preparation. The total length of the 'unreplicated' stem portion

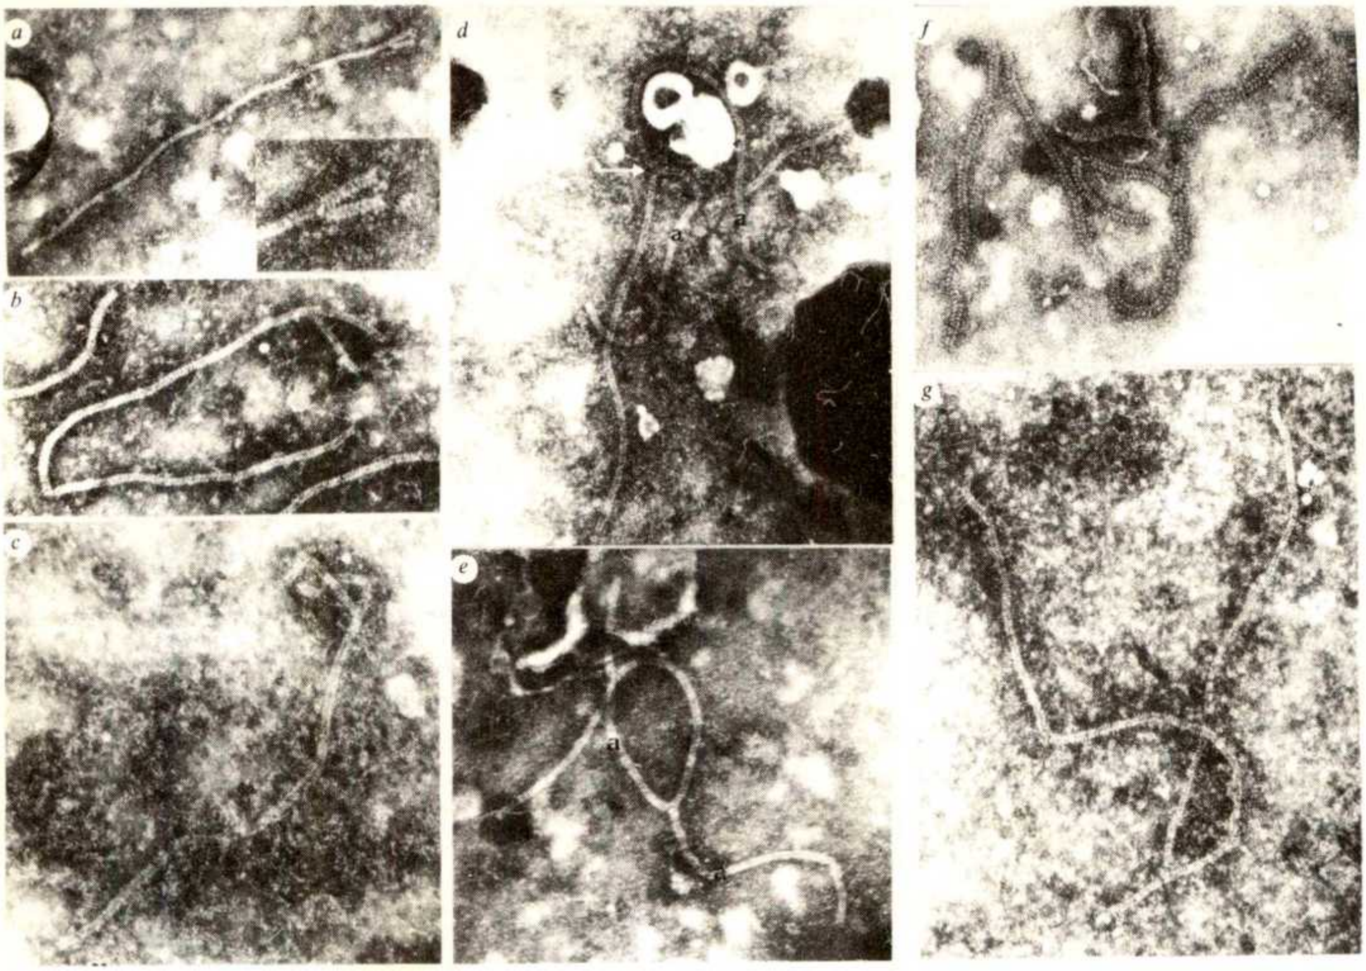

Fig. 1 Y-form nucleocapsid at various stages of replication. Lengths of arms and stems, respectively. *a* ×39,600 (inset ×99,000). 0.07 μm, 0.07 μm and 1.45 μm. Nine turns of capsid helix on each arm. *b* ×66,000. 0.12 μm (21 turns), 0.13 μm (22 turns) and 1.34 μm. *c* ×92,400. 0.18 μm, 0.16 μm and 0.7 μm. *d* ×66,000. 0.73 μm, 0.73 μm and 0.6 μm. Arrow indicates junction of arms (**a**) and stem. *e* ×66,000. 0.5 μm, 0.53 μm and 0.8 μm. *f* ×66,000. 0.34 μm, 0.33 μm and 1.21 μm. *g* ×66,000. 1.26 μm, 1.07 μm and 0.13 μm.

plus one arm was between 0.8 and 1.6 μm. This is similar to the range of lengths found for non-replicating nucleocapsids in the same preparations. The variation in length of the 'unreplicated' portion of the Y-forms was apparently random. Molecules adventitiously joined in suspension or on drying on the grid can generally be distinguished by the overlapped appearance of the junction and by the lack of relationship between the lengths of the three arms.

A feature apparent in most (22 out of 26) of the 'replicating forms' is that the capsomeres in one arm of the Y-forms have the opposite orientation to those in the other (Fig. 1*a*, *b*, *f*, *g*). This might be expected from the presumed opposing polarities of the encapsidated complementary RNA chains. If, however, one of the arms had turned over, the orientation of capsomeres would be the same in both arms (Fig. 1*d*, *e*). Assuming that the RNA is replicated by presently known processes, the new chain beginning with the 5′ end would be copied from the 3′ end of the parent molecule. By reference to Fig. 1*b*, it can be seen that this allows identification of the 3′ end of the nucleocapsid as the end with the convex orientation of capsomeres.

The structural features at the junction are not yet apparent although some alteration of capsid arrangement is suggested by Fig. 1*a*, *b* and *g*. Better preserved preparations and higher resolution are required for further study.

Rigid proof that the Y-forms represent the true replicative form may be difficult to obtain since they occur only at very low frequency, presumably owing to the rapid rate of replication. Our attempts to increase the number of Y-forms by arrest of nucleocapsid synthesis by rapid freezing and by the use of inhibitors have so far been unsuccessful. These preliminary results, however, support the idea that the nucleocapsid is replicated from an intact nucleocapsid template with local unwinding to expose the enclosed RNA and rapid assembly of progeny nucleic acid and protein[7].

We previously reported the presence of circular nucleocapsid molecules in measles-infected cells[9]. Similar circular molecules, which were thought to be end-to-end aggregates of linear nucleocapsid, had been already reported for another paramyxovirus, NDV, by Compans and Choppin[10] but we were unaware of their work. It seems likely from the results presented here that circular nucleocapsids do not function in the replication of the normal linear nucleocapsid population. We have, however, found rare circular molecules which appear to have attached tails in even lower proportion than the Y-forms. These may represent templates functioning in a rolling-circle type of mechanism as previously suggested[9] but this requires further study.

This work was supported by an MRC Programme grant. We thank Mr G. Clarke and Mr T. McLaughlin for assistance.

Presence of 1,25-dihydroxyvitamin D_3-glycoside in the calcinogenic plant *Cestrum diurnum*

A DISEASE clinically and morphologically similar to vitamin D-intoxication, characterised by hypercalcaemia and extensive soft tissue calcification, has been described in grazing animals and linked to the ingestion of leaves from several plant species including *Cestrum diurnum* (*C.d.*)[1-3] and *Solanum malacoxylon*[3]. Early reports indicated that activity resembling the hormonal form of vitamin D_3, 1,25-dihydroxyvitamin D_3 (1,25-$(OH)_2D_3$), existed in extracts of both of these plants[3-5]. The active calcitropic principle from *S. malacoxylon* has been identified as a 1,25-$(OH)_2D_3$-glycoside[6-8]. We report here the isolation and identification of a 1,25-$(OH)_2D_3$-glycoside in *C.d.* It is proposed that this principle accounts for the hyperabsorption of calcium found in animals eating this plant.

We have previously reported that the ingestion of *C.d.* results in increased calcium absorption and induced calcium binding protein (CaBP) synthesis in chicks fed a diet containing strontium[5]. Strontium blocks the renal 1-hydroxylase enzyme which converts vitamin D_3 to active 1-hydroxylated metabolites[9]. Hence, any plasma 1-hydroxylated-D-vitamins in these animals must originate exogenously. With the development of a specific radioreceptor assay for 1,25-$(OH)_2D_3$ (refs 10–12), it is now possible to directly assess the 1,25-$(OH)_2D_3$ activity in the plasma of chicks after *C.d.* administration. Table 1 reveals that after a single oral dose of *C.d.*, there is a rapid increase in plasma 1,25-$(OH)_2D_3$-like radioreceptor activity followed by an elevation in duodenal CaBP. Within 12 h the 1,25-$(OH)_2D_3$-like activity increases about eightfold over the normal physiological concentration of the hormone in chicks (5.2 ng dl^{-1}) (ref. 14). These observations suggest that the biologically active calcaemic principle of *C.d.* might be 1-hydroxylated in the native plant, since the 1-hydroxyl moiety of vitamin D analogues has been shown to be essential for efficient binding to the chick intestinal receptor protein used in the radioreceptor assay. Consequently, when this calcaemic plant factor is ingested by animals, it might circumvent the stringent renal regulation of the circulating level of the 1,25-$(OH)_2D_3$ hormone.

Celite liquid–liquid partition chromatography[12] was then used to analyse plasma from chicks treated with *C.d.* Aliquots of plasma obtained from the experiment described in Table 1 were combined with tracer radioactive 1,25-$(OH)_2D_3$ and chromatographed on Celite (Fig. 1*a*). The coincident migration of authentic hormone with the radioreceptor activity from the chick plasma further substantiates that *C.d.* must contain a factor very similar, if not identical, to 1,25-$(OH)_2D_3$.

Table 1 Appearance of plasma 1,25-$(OH)_2D_3$-like activity and intestinal calcium binding protein (CaBP) in chicks given an oral dose of *C. diurnum*

Time after dose (h)	Plasma radioreceptor activity (ng equivalent 1,25-$(OH)_2D_3$ per 100 ml)	Intestinal CaBP (μg per mg protein)
0	<0.5	0
6	24	<0.3
12	43	1.4
24	18	6.9

White leghorn cockerels were placed on a diet[5] supplemented with 1.2 IU vitamin D_3 per g, 2.56% Sr, 0.05% Ca and 0.76% P. Each chick received an oral dose of *C.d.* extract equivalent to 2 g original dried leaf. Plasma from five chicks was pooled, purified, and assayed for 1,25-$(OH)_2D_3$-like receptor activity as previously described[12]; data represent the mean of triplicate assays for each pooled sample. Duodenal CaBP was quantitated by radial-immunoassay[13] in supernatant fractions of homogenised duodenal mucosa, and the mean data expressed as μg CaBP per mg total supernatant protein.

Contrary to this idea that the plant factor is identical to 1,25-$(OH)_2D_3$ is the slightly slower observed appearance of intestinal CaBP after administration of *C.d.* as compared with that observed following administration of the pure hormone[15]. Also, we could not demonstrate the receptor activity for the crude *C.d.* extract that was predicted by bioassay of this material[5]. These observations suggested that some preliminary modification of the *C.d.* principle might be required in the animal before receptor binding and consequent biological activity. We have previously shown that hydrolysis of the

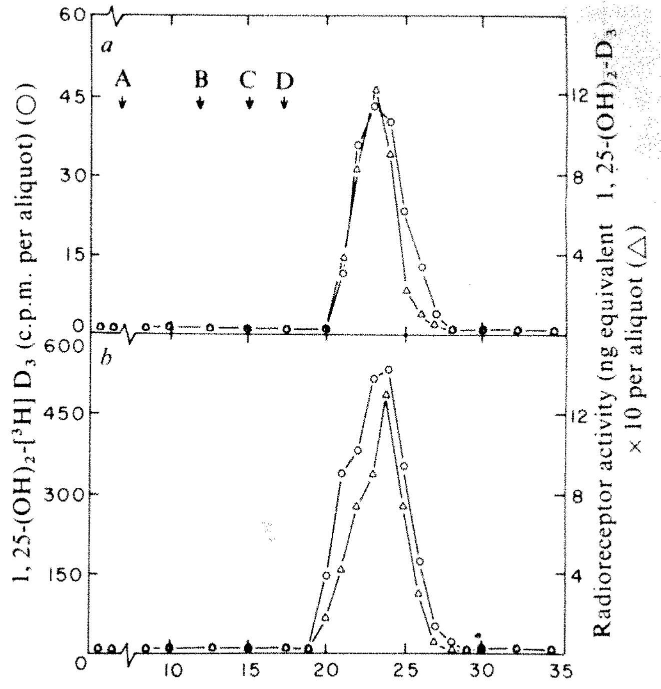

Fig. 1 Comigration on Celite of the lipid soluble 1,25-$(OH)_2D_3$-like factor from *C.d.* with authentic tritiated hormone. *a*, After an oral dose of *C.d.*, chick plasma was extracted with $CHCl_3$:CH_3OH (1:2) and partially purified via Sephadex LH-20, silicic acid, and microCelite chromatography[12]. The 1,25-$(OH)_2D_3$-like material from *C.d.* co-eluted with standard, tritiated 1,25-$(OH)_2D_3$ (5500 c.p.m., 0.32 ng) in each of these column systems (data not shown). The material was then subjected to a long Celite column (1×40 cm) (*a*) and the radioreceptor activity was compared to the migration position of the 1,25-$(OH)_2[^3H]D_3$ internal marker. Other vitamin D forms migrate as indicated: A, 25-hydroxyvitamin D_3; B, 24,25-dihydroxyvitamin D_3; C, 25,26-dihydroxyvitamin D_3; D, 1,25-dihydroxyvitamin D_2 (ref. 12). *b*, Dried *C.d.* leaf (300 g) was extracted with $CHCl_3$ (discarded) and the nonsoluble material was further extracted with $CHCl_3$:CH_3OH (1:2). The active material was precipitated with acetone and the pellet subsequently redissolved in $CHCl_3$:CH_3OH (1:2). After removal of this solvent, the material was suspended in citrate–phosphate buffer (*p*H 5.0) and 500 mg of mixed glycosidases derived from the liver of the sea worm, *Charonia lampas* (Miles), was added. The mixture was incubated for 16 h at 37 °C under N_2 and the material was placed into a separatory funnel with H_2O:CH_3OH:$CHCl_3$ (1:1:1.5) and the phases allowed to separate. The lower $CHCl_3$ phase was then combined with three $CHCl_3$ washes of the upper phase and dried in a rotary evaporator under N_2 in a vacuum. Bioassay identification of the active fraction was carried out by administration to strontium-fed chicks and measuring intestinal calcium absorption and calcium binding protein[5]. Tracer 1,25-$(OH)_2[^3H]D_3$ (15,000 c.p.m., 0.875 ng) was added to the dried, hydrolysed material and the mixture was pre-purified by silicic acid chromatography (1×20 cm) eluted with ether: acetone (95:5 v/v) under N_2 pressure. The active radioreceptor fractions were combined and purified by Sephadex LH-20, microCelite chromatography and, finally (*b*) a 1×40 cm Celite liquid-liquid partition column[12].

calcaemic factor from *S. malacoxylon*, by a mixture of glycosidases, has been a prerequisite for receptor binding[6]. Thus we exposed (*in vitro*) an extract of *C.d.* to this same mixture of glycosidases from the liver of the seaworm, *Charonia lampas*, and obtained a lipid-soluble biologically active fraction. This hydrolysed material was then purified by a series of chromatographic columns (see legend of Fig. 1). The final step was Celite chromatography and the 1,25-$(OH)_2D_3$-like binding activity comigrated with authentic tritiated 1,25-$(OH)_2D_3$ (Fig. 1*b*), as also observed with the purified plasma principle from *C.d.*-fed strontium-inhibited chicks (Fig. 1*a*). It is thus reasonable to assume that the *in vitro* hydrolysis by the mixed glycosidase preparation resembles a similar hydrolysis which takes place *in vivo*, both liberating an active fragment indistinguishable from 1,25-$(OH)_2D_3$ by all of the chromatographic systems used (see Fig. 1 legend).

The chromatography scheme used analytically in these comigration studies was then used to purify sufficient quantities of *C. lampas*-hydrolysed material to allow for further characterisation of the *C.d.* factor. The pooled peak fractions from the final Celite column exhibited an ultraviolet absorption spectrum identical to that of 1,25-$(OH)_2D_3$ (ref. 16). Quantitation of the material was achieved with the radioreceptor assay which indicated that 1.2 µg of 1,25-$(OH)_2D_3$-equivalents were present. This represents the total activity derived from 300 g of dried *C.d.* leaf, but this should not be used as an indication of the concentration of the factor in *C.d.*, since we were unable to assess yields during the early extraction procedures.

This evidence for the 1,25-$(OH)_2D_3$-like nature of the *C.d.* principle led us to compare the mass spectrum of the hydrolysed purified *C.d.* extract to that of crystalline 1,25-$(OH)_2D_3$ by gas chromatography/mass spectrometry (GC/MS). D-vitamins are known to pyrolyse during gas chromatography yielding two isomers—the 'pyro-' and 'isopyro-' forms, as a result of closure of the B-ring[8,17]; this fact is germane to understanding the fragment pattern. Figure 2*a* (inset) depicts the total ion current obtained with 1.2 µg of synthetic 1,25-$(OH)_2D_3$. The major peak of ion current emerges from the column at 7 min (arrow) and represents 1,25-dihydroxy*pyro*vitamin D_3; the second peak represents 1,25-dihydroxy*isopyro*vitamin D_3. The mass spectrum (Fig. 2*a*) of the major peak (arrow) shows characteristic fragments at *m/e* 380, 362, 251, 209, 155, 141, 105, 69, 59, and 55. A similar mass fragment pattern was observed for the second, '*isopyro*', peak of total ion current (data not shown). Figure 3 shows 1,25-dihydroxy*pyro*vitamin D_3 and the cleavages of the ABCD ring system which are typical of classic steroids[18] and probably produce the mass fragments actually observed (Fig. 2*a*) for 1,25-$(OH)_2D_3$.

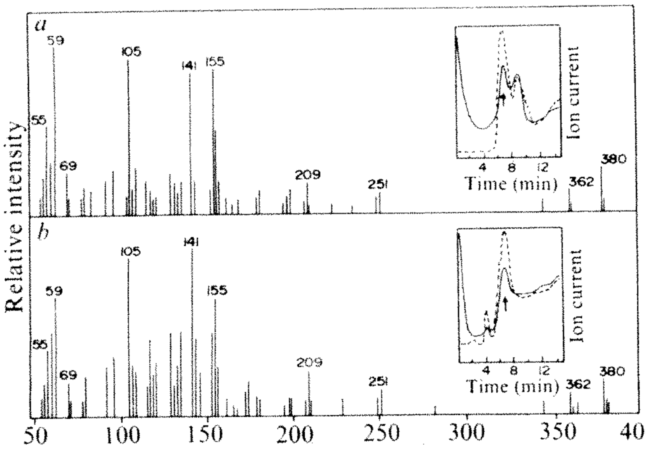

Fig. 2 Analysis of 1,25-$(OH)_2D_3$ and the lipophilic fragment of *C.d.* by gas-liquid partition chromatography and mass spectrometry. *a*, Gas chromatogram/mass spectrum of 1.2 µg of synthetic 1,25-$(OH)_2D_3$. *b*, Gas chromatogram/mass spectrum of 1.2 µg of purified hydrolysed *C.d.* Insets show gas chromatographic traces of total ion current (solid line) and ion current at *m/e* 380 (broken line). The arrows indicate the peak fractions which were characterised by mass spectrometry. These analyses were performed on a Model 3300-6110 Finnigan GC/MS with quadrapole analyser in the electron impact ionisation mode, equipped with a 2 mm × 50 cm, 3% OV-7 (100-120 mesh) glass column. Other parameters: injection port temperature, 260 °C; column temperature, 245 °C initial, 8 °C per min programmed increase; sample application in 5 µl double distilled ethanol (100%).

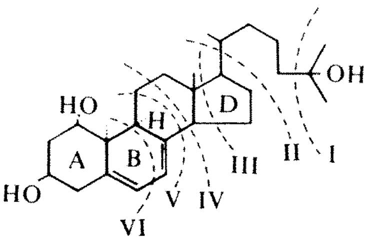

Fig. 3 Proposed fragmentation pattern for 1,25-dihydroxy*pyro*vitamin D_3. The molecular weight of 1,25-$(OH)_2D_3$ is 416, but the parent peak of the GC/MS, which is at *m/e* 380, represents the native molecule minus two hydroxyl groups that are lost in the form of H_2O during heating. Loss of the third hydroxyl in the form of H_2O yields the fragment at *m/e* 362. Cleavage I gives a major peak at *m/e* 59 by removal of the portion of the side chain; and, removal of the entire sidechain (111 AMU) from the fragment at *m/e* 362 (cleavage II) yields the peak at *m/e* 251 which is the fused ABCD ring array. As discussed by Budzikiewitz and coworkers[19], steriod ring systems are commonly cleaved between C_{14-15} and C_{13-17} (cleavage III) losing 42 AMU and leaving a fragment at *m/e* 209 in this instance. The *m/e* 209 fragment (or *m/e* 210 resulting from common hydrogen rearrangement in steroids[19]), now serves as a source for three complementary pairs of fragments which comprise the important remaining peaks of the 1,25-$(OH)_2D_3$ mass spectral pattern. These pairs include: *m/e* 155 and 55 resulting from cleavage at IV; *m/e* 141 and 69, from cleavage at V; and *m/e* 105 which represents both fragments generated from cleavage at VI. It should be emphasised that cleavages III-VI are characteristic cleavage positions predicted from the mass spectra of other steroids[18,19].

The inset of Fig. 2*b* illustrates the total ion current trace and the monitored ion current at *m/e* 380 obtained from gas chromatography of 1.2 µg of purified hydrolysed *C.d.* factor. Again, the major peak (arrow) emerges at 7 min, resolved from sample contaminants which apparently obscure any observation of the '*isopyro*-' form of *C.d.* Mass spectral analysis of this peak (Fig. 2*b*) reveals a fragment pattern equivalent to that obtained for 1,25-$(OH)_2D_3$. The coincident migration of the active lipophilic fragment of *C.d.* with 1,25-$(OH)_2D_3$ on the gas chromatographic column, and the identical mass spectra of the resulting peaks convincingly demonstrates that 1,25-$(OH)_2D_3$ is present in *C.d.*, although the steroid apparently exists in the native plant in the form of a glycoside.

Synthesis, storage and release of acetylcholine by a noradrenergic pheochromocytoma cell line

DEVELOPING neural crest tissues show a certain degree of plasticity with respect to neurotransmitter synthesis. For example, heterotopic transplants of presumptive noradrenergic tissue may develop cholinergic properties and vice versa[1,2]. Also, monolayer cultures of rat sympathetic neurones which synthesise catecholamines may be influenced to synthesise acetylcholine by exposure to ganglionic non-neuronal cells or to medium conditioned by such cells[3,4]. Recently, a clonal cell line (designated PC12) was established[5] from a transplantable rat adrenal medullary pheochromocytoma[6]. This line expresses many characteristic properties of neural-crest-derived noradernergic adrenal chromaffin cells and sympathetic neurones, including synthesis, storage, uptake and specific release of catecholamines[5,7,8]. In addition, within several days after their exposure to nerve growth factor (or NGF, a protein which influences the growth and development of normal sympathetic neurones[9]), PC12 cells cease mitotic activity and extend long, neuronal processes[5]. We show here that noradrenergic cultures of PC12 cells can also synthesise, store and release acetylcholine.

PC12 cultures, maintained as described before[5,7] were assayed for choline acetyltransferase (CAT) activity by the method of Fonnum[10]. Assays performed in the absence of choline or in the presence of 100 μM naphthylvinyl pyridine (a specific inhibitor of CAT), gave values similar to tissue-free blanks, thus indicating the specificity of the activity for CAT and excluding the presence of carnitine acetyltransferase[11]. As shown in Fig. 1*a*, *b*, the specific activity (s.a.) of CAT varied markedly with cell density. At maximal cell density, specific activities reached 500–600 pmol per min per mg protein. This level is comparable with magnitude to that observed in rat brain tissue[12] but is lower than levels reported in chicken ciliary ganglia[13] (~50 nmol min^{-1} mg^{-1}). The increase in the s.a. of CAT in PC12 cultures occurred mainly during the logarithmic stage of cell growth and then plateaued when the cultures reached the stationary phase (Fig. 1*a*, *b*). Thus, the s.a. of CAT is apparently related to cell density rather than to the rate of cell division. As further evidence of this, CAT activities in cultures of division-arrested PC12 cells (produced by treatment with 1 μM cytosine arabinoside) were comparable to those in logarithmic growing cultures of similar density (see zero time in Fig. 1*c*, for example). Such findings suggest that the increase in specific CAT activity with increased cell density may be due to autoconditioning in a manner analogous to that observed for

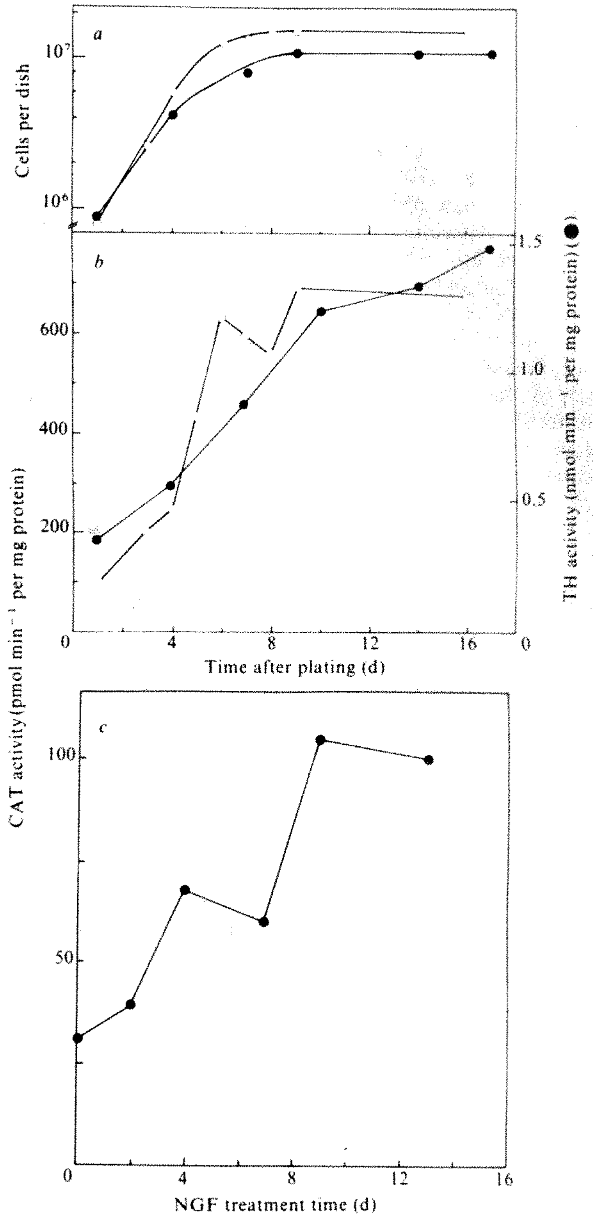

Fig. 1 Regulation of CAT activity in PC12 cells. *a*, *b*, Variation of specific activities of CAT (○) and TH (●) as a function of cell density. *a*, Cell number; *b*, specific enzyme activities. Cells were plated in collagen-coated 35-mm dishes as previously described[5]. In this, and in all subsequent experiments, the culture medium was changed every other day. At indicated times, cells were collected from duplicate sister cultures and assayed in duplicate for cell number and enzyme activity. CAT activity was measured according to Fonnum[10]; TH was measured according to Black *et al.*[19], with concentrations of tyrosine and DMPH_4 of 200 μM and 1 mM, respectively. Specific activities are based on protein levels of homogenates estimated (with a bovine serum albumin standard) by the methods of Lowry *et al*[20]. (TH assays) or McGuire *et al.*[21] (CAT assays). Variation in specific activities between duplicate cultures in this and other experiments was less than 15%. *c*, Effect of NGF treatment on the specific activity of CAT in division-arrested PC12 cells. Non-dividing PC12 cells were produced as follows. Stationary phase dishes (100 mm) of PC12 cells were exposed to 1 μM cytosine arabinoside (ara-C) for one week. The cells which survived this treatment (about 20% of the original population) were found to be non-dividing and to survive in the presence of ara-C for at least 1 month. The ara-C-selected cells were then subcultured into 35 mm collagen-coated dishes at low cell density (1.2×10^5 per dish) in the presence of ara-C. At various times after plating, NGF was added to the medium of pairs of sister cultures. On day 13, cells were collected from all cultures and assayed in duplicate for CAT. Cell counts confirmed that the cell number in both NGF-treated and untreated cultures did not change significantly during the course of the experiment.

induction of CAT in cultures of sympathetic neurones by non-neuronal cells[3].

The presence of CAT activity in PC12 cells was not only limited to tissue cultures; tumours of PC12 cells grown subcutaneously in rats had CAT activities on the order of 200 pmol min^{-1} mg^{-1}. Furthermore, we have detected CAT activity in tissue from two catecholamine-secreting human pheochromocytomas (unpublished).

Parallel experiments on PC12 cultures revealed that the s.a. of tyrosine hydroxylase (TH), the first enzyme in the synthetic pathway of catecholamines, also increased as a function of cell density (Fig. 1*a*, *b*). Thus, both CAT and TH seem to be similarly inducible in PC12 cultures and to be at maximal levels at high cell density. Such findings lead to the question of whether both neurotransmitter synthesising systems coexist in the same cells. Several pieces of evidence suggest (but do not unequivocally prove) that this is so. First, as judged by histochemical localisation, virtually every PC12 cell in high density cultures contains catecholamines[5,14]. Secondly, ultrastructural studies of PC12 cultures have revealed that dense-core granules (of the type thought to contain catecholamines) and small agranular vesicles (of the type usually considered to contain acetylcholine) are present in the same cells[5,14]. To test further the possibility of dual neurotransmitter synthesis, PC12 cells (250 generations after isolation) were subcloned as previously described[5]. Table 1 reveals that of the single-cell subclones isolated and tested at high cell density, all seven had high levels of TH activity while two also displayed reasonably high levels of CAT activity. This suggests that although the PC12 line is heterogeneous with respect to CAT activity, at least a given subpopulation of cells contains both enzymes. Further experiments will be needed to determine whether such subclones will themselves remain homogenous for CAT activity and whether CAT activity may be induced (either spontaneously or by treatment with conditioned media) in the subclones with low levels of this enzyme.

As mentioned above, PC12 cells respond to NGF by cessation of replication and extension of neurites. To access the effect of NGF treatment on CAT activity in PC12 cells and to dissociate such effects from those on cell division (and thus cell density as well), the following experiment was performed. A stable population of division-arrested PC12 cells was produced by treatment with 1 μM cytosine arabinoside (ara-C) for one week. Such cells were then subcultured at low density (1.2×10^{5} per 35-mm dish) in the presence of ara-C, treated with 2.5 S NGF (ref. 15) for various periods and then harvested and assayed for CAT activity. The ara-C treated cells began to extend neurites within 2 d of treatment with NGF, but did not do so in its absence. The results of this experiment (Fig. 1*c*) revealed that the s.a. of CAT underwent a significant increase within several days of NGF treatment. Furthermore, the time course of this increase roughly paralleled that of neurite outgrowth. No conclusions regarding a causal relationship between the two events could be drawn, however.

Table 1 Enzymatic activities of subclones of PC12 cells

Subclone	Specific enzymatic activity (pmol per min per mg protein) TH	CAT
1A	2,866	11
2B	3,468	170
3A	2,315	15
3B	1,847	8
D2	2,522	153
B1	3,054	19
C2	2,193	14

Single cell subclones were isolated as previously described[5]. Clones were grown to high density (20 generations after initial isolation), harvested and assayed for specific enzymatic activity. Results are means of duplicate assays on first (TH) or first and second (CAT) passage cultures. Lower limit of sensitivity of CAT assay was 0.5 pmol per min per mg protein.

Table 2 Synthesis and storage of ACh by PC12 cultures

	Untreated	NGF-treated
CAT activity		
pmol per min per mg protein	440±17	520±20
pmol per min per 10^6 cells	31±2	83±5
ACh content		
pmol per mg protein	1,335±77	5,594±637
pmol per 10^6 cells	93±7	892±146

Data are mean values (±s.e.m.) based on assays performed in quadruplicate on NGF-treated (22 d in the presence of 50 ng ml^{-1} NGF, 3.5×10^{6} cells per dish) and high density untreated (13.6×10^{6} cells per dish) PC12 cultures.

Experiments were also carried out to assess whether PC12 cells could store the acetylcholine (ACh) they synthesised and whether NGF treatment would affect this capacity. Since PC12 cells (NGF-treated and untreated) contain high levels of cytoplasmic acetylcholinesterase activity (F. Rieger, P. Taylor and L.A.G., in preparation), it is likely that any endogeneous ACh is stored rather than free in the cytoplasm. Accordingly, cultures of NGF-treated and of high-density NGF-untreated PC12 cells with comparable specific activities of CAT were assayed for their contents of ACh by the sensitive radioassay of Goldberg and McCaman[16] (Table 2). Although both types of cultures contained substantial quantities of ACh (nmol per mg protein), those treated with NGF contained three- to fourfold more ACh per mg protein and an average of about tenfold more per cell. One possible basis for this difference in content is that NGF-treated PC12 cells contain many more small agranular vesicles than do untreated cells[5,14].

The data in Table 3 show the results of experiments which demonstrate that PC12 cells can not only synthesise and store ACh, but also release it on exposure to a depolarising medium. While release of ^{3}H-ACh was significantly enhanced in the presence of 51.5 mM K^+, release of ^{3}H-choline was not. In three separate experiments, the proportion of the cellular contents of labelled ACh released by elevated K^+ was between 15 and 20%. We have previously obtained comparable results for the release of noradrenaline from PC12 cells in similar conditions[7]. Thus, it is possible that both neurotransmitters may be secreted by the same cells. Evidence for such a dual release has been presented for rat sympathetic neurons in culture[17]. Finally, as shown for nerve endings and synaptosomes (ref. 18) the K^+-induced increase in release of ACh from PC12 cells was blocked in media either free of Ca^{2+} or containing elevated (10× control) Mg^{2+}.

In conclusion, cultures of the noradrenergic PC12 line of rat pheochromocytoma may synthesise, store and release significant quantities of ACh. The duality of neurotransmitter function shown by this type of cell may resemble, as well as have common origins with, that shown by other neural crest derivatives of normal and neoplastic origin. In this context, PC12 cells should prove useful in the study of various aspects of acetylcholine metabolism as well as the regulation and specification of neurotransmitter properties in developing neurones.

We thank Mrs M.-N. Chou for assistance with tissue culture and Drs P. Patterson, S. R. Snodgrass, H. Thoenen and N. Uretsky for helpful discussion. This work was

Table 3 Release of ACh from PC12 cells

Release conditions	d.p.m. released per culture of Choline	ACh
Control	27,750±5,550	6,110±2,830
51.5 mM K$^+$	33,860±2,890	21,650±3,330
51.5 mM K$^+$, 0 Ca^{2+}	28,310±2,220	4,440±2,940
51.1 mM K$^+$, 10×Mg^{2+}	30,530±2,810	11,100±2,330
Intracellular content before release	71,040±6,660	108,225±8,800

Sister cultures (collagen-coated 35-mm dishes containing 2×10^6 cells) of NGF-treated (14 d) PC12 cells were washed free of culture medium and incubated (at 37 °C in this and all subsequent incubations) for 30 min in 1 ml of HEPES-buffered Ringers saline (KRH) (ref. 7) supplemented with (methyl-^{3}H)-choline (10.7 μCi per dish; s.a. = 2.5 Ci mmol^{-1}). The 'loading' medium was then removed and the cultures were washed three times with saline and then maintained for 1 h with 1.5 ml of culture medium RPMI 1640 supplemented with 2% horse serum to allow washout of unbound ^{3}H-choline and its derivatives. Cultures were then pre-incubated for 15 min in KRH before successive 20-min incubations with 1 ml aliquots of KRH (control medium lacking Ca^{2+} or with 10×Mg^{2+} also gave comparable final values) and then KRH modified as described above to contain 51.5 mM K$^+$ and the indicated levels of Ca^{2+} and Mg^{2+}. Eserine (30 μM) was also present during incubations to inhibit cellular acetylcholine esterase. The levels of ^{3}H-choline and ^{3}H-acetylcholine released by and contained within the cells were determined as follows by modifications of previously described procedures[10,16,18,22]. The KRH fractions were placed on ice immediately after the incubations and shortly thereafter extracted with 3 ml of heptan-3-one containing 20 mg ml^{-1} tetraphenylboron. Choline and ACh were then extracted from the organic phase in 1 ml of 0.4 M HCl which was then lyophilised to dryness. Choline and ACh remaining within the cells after release was collected by homogenising in 500 μl of 1 M formic acid–acetone (15:85 v/v). The homogenate was centrifuged at 1000*g* for 5 min and the supernatant was taken to dryness *in vacuo*, resuspended in 1 ml of KRH and then extracted and lyophilised as above. Each dry sample was re-dissolved in 40 μl of chromatography solvent containing authentic carrier choline and ACh (each 10 mM) and 25 μl of this was spotted onto thin layer chromatography (TLC) plates (Eastman no. 6064). After chromatography as previously described[22] the plates were dried and the locations of carrier ACh and choline were identified by exposure to I$_2$ vapour. Each chromatography track was then cut into 5-mm horizontal strips which were placed in separate glass vials and extracted with 1 ml of 0.1 M HCl for 30 min. Liquid scintillation fluid (Instagel-Packard) was added to the vials which were then assayed for radioactivity at a counting efficiency of 23%. Data are presented as radioactivity which co-chromatographed with authentic ACh and choline. Recoveries were estimated on the basis of that of samples of ^{3}H-choline which were similarly processed (ACh has been shown previously to have a comparable recovery to that of choline[18]). Values are given (±s.d.) for an experiment with seven cultures (three for 51.5 mM K$^+$ and two each for 0 Ca^{2+} and 10×Mg^{2+}). Comparable release data were obtained in two other separate experiments.

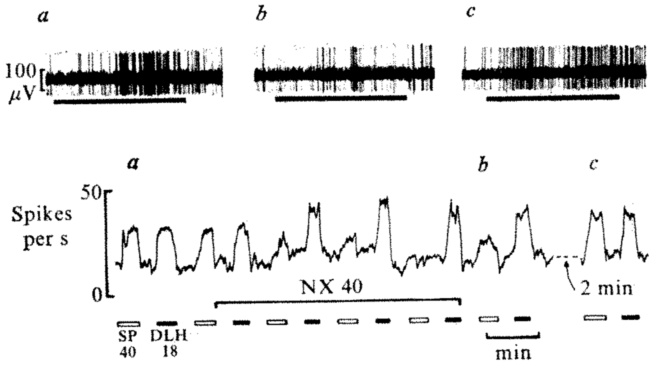
Substance P and opiate receptors

IT has recently been demonstrated that the undecapeptide substance P (SP) produces analgesia in mice when administered intracerebroventricularly (i.v.) or intraperitoneally (i.p.)[1]. This effect of SP was reversed by naloxone indicating the possible involvement of central opiate receptors. The possibility that SP may act on opiate receptors at the single neurone level has been investigated on spinal Renshaw cells in the cat. These cells possess stereo-specific opiate receptor sites[2,3]. The results obtained show that SP excites Renshaw cells and that this action is antagonised by naloxone. Substance P also reduced the excitation of Renshaw cells by acetylcholine.

Experiments were performed in 12 cats anaesthetised with pentobarbitone sodium (35 mg kg^{-1} i.p. initially and supplemented i.v. as required). Blood pressure was continuously monitored and body temperature was maintained at 37 °C. A lumbar laminectomy was performed and the cut central ends of S1 or L7 ventral roots were stimulated to identify Renshaw cells. Extracellular action potentials were recorded *via* the centre barrel (4M NaCl) of a seven barrel micropipette (tip diam. 6 μm). The outer barrels of the micropipette contained aqueous solutions of the following drugs to be ejected electrophoretically: substance P (0.0007 M in 0.165 M NaCl), morphine sulphate (0.05 M in 0.165 M NaCl), naloxone hydrochloride (0.1 M), acetylcholine chloride (0.5 M), DL-homocysteic acid (0.2 M, *p*H 7.2), NaCl (0.165 M).

Substance P excited 17 of 34 Renshaw cells when ejected with cationic currents (40–80 nA, mean 58 nA). Excitation by SP was invariably marked, of rapid onset and comparable to that of DL-homocysteic (see Fig. 1). On, five cells however, the excitatory effects of SP were of slower onset and outlasted the durati on of electrophoretic ejection by 5–20 s. The differences in the time course of SP excitation in the present experiments and the inconsistent effects of SP in other studies[5] may be associated

Fig. 1 Rate meter record (spikes per s against min) illustrating excitation of a Renshaw cell by alternate iontophoretic ejection of substance P (SP 40 nA) and DL-homocysteic (DLH, 18 nA). Ejection of naloxone (NX 40 nA) from an adjacent barrel of the same pipette reversibly reduced SP but not DLH-induced excitation. Extracellular spike records *a*, *b* and *c* of substance P effects correspond to the labelled rate meter response. The duration of iontophoretic ejections is indicated by the horizontal bars below each record. The spike records also show that SP excitations were not accompanied by changes in spike amplitude.



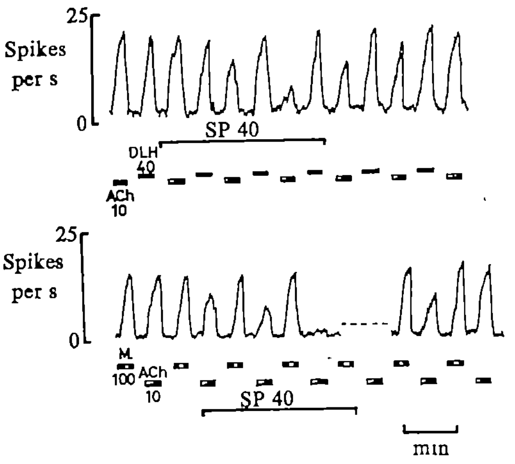


Fig. 2 Rate meter record showing excitation by alternate ejections of acetylcholine (ACh 10 nA) and DLH (40 nA). Prolonged electrophoretic administration of substance P had no effect on the spontaneous firing of this cell but SP (40 nA) reversibly reduced ACh and not DLH responses. The lower record from another Renshaw cell shows that a similar prolonged ejection of SP again reversibly reduced ACh excitation but had little affect, at this current (40 nA), on morphine (100 nA)-induced excitation. Recovery of ACh sensitivity was more prolonged—the dashed line indicates a break of 3 min. A higher current of SP also reduced excitation by morphine on this cell (not shown).

with variable rates of release from individual micropipettes[4,5]. No desensitisation or tachyphylaxis of SP-induced excitation was observed though this phenomena may be a feature accompanying SP excitation in other areas of the CNS (refs 4–8).

Substance P-induced excitation was reversibly reduced by the narcotic antagonist naloxone (30–40 nA, mean 36 nA) on five of the six neurones, whereas the excitatory action of DL-homocysteic was unaffected on three cells and slightly enhanced on the others (Fig. 1). On the same cells, the excitatory effects of morphine and acetylcholine were also reversibly reduced by naloxone in agreement with earlier findings[2,3,9].

In contrast, prolonged ejections of SP with relatively low currents (20–40 nA, mean 30 nA for 2 min or more) markedly reduced the sensitivity of Renshaw cells to acetylcholine while having little effect on spontaneous firing or DL-homocysteic-induced excitation of the same cells (Fig. 2, upper record) This depression of acetylcholine sensitivity was often prolonged (Fig. 2, lower record). Similar results were obtained from 14 other Renshaw cells. This interaction of SP has been noted in another laboratory[10] and we have previously described a similar reduction of acetylcholine sensitivity of Renshaw cells by another peptide, enkephalin[11].

In tests on three cells, SP antagonised both morphine and acetylcholine excitation. However, in each cell the acetylcholine responses were reduced by lower ejecting currents of SP (see Fig. 2). Interestingly, enkephalin also differentiates between excitation induced by morphine and acetylcholine[11].

The present results show that the excitatory effects of SP on Renshaw cells are remarkably similar to the excitatory effects of enkephalin and to the stereospecific effects of morphine[2,3,11]. Additionally, the responses to these three substances are antagonised by naloxone. Thus, these excitatory effects of SP are consistent with an action on opiate receptors. Whether the activation of such receptors on the Renshaw cell is related to the analgesic actions of SP[1] or opiates (see refs 3, 9) is uncertain. However, it may be significant that the regional distribution of SP concentration and opiate receptor binding sites in other brain areas is similar[12,13]. Thus, activation of opiate receptors in these areas might explain the analgesic actions of SP more readily.

The reduction of acetylcholine sensitivity produced by SP might be unrelated to an action at opiate receptors since morphine enhances acetylcholine responses on Renshaw cells[3,9]. However, this action of SP has been demonstrated in several brain areas[5,8] and is shared by other peptides, for example, enkephalin[11] which suggests that polypeptides should be considered to exert a multiplicity of actions at central neurones.

Evidence for a cyclic nucleotide-mediated calcium flux in motor nerve terminals

WE recently suggested that a cyclic nucleotide system might participate in neuromuscular transmission by regulating the flux of calcium and/or sodium into the nerve ending[1–4]. The purpose of the present investigation was to refine this postulate by studying the interactions between the cyclic nucleotide system and reagents that affect calcium and sodium flux in nerve terminals differentially. Recording from single motor axons of cat soleus nerves *in vivo*, we found that the calcium antagonists verapamil (iproveratril)[4,5] and lanthanum[6] blocked stimulus-bound repetitive action potentials (SBR) produced by the administration of dibutyryl (db) cyclic AMP and sodium fluoride, whereas tetrodotoxin (TTX) did not alter the nerve or muscle response to these reagents. The results suggest that an intraterminal cyclic nucleotide system may regulate calcium flux into the motor nerve ending.

The preparation has been described before[7]. Cats were anaesthetised with 70 mg kg^{-1} α-chloralose and the popliteal fossa was exposed. All branches of the popliteal artery except that which supplies the soleus muscle were occluded and all branches of the tibial nerve except that to the soleus muscle were severed. Both heads of the gastrocnemius muscle were removed and the tendon of the soleus muscle was attached to a strain gauge. A dorsal laminectomy was performed, the ventral root of L7 was cut and its distal stump was split until a strand containing a single functional axon to the soleus muscle was found. This strand was placed over bipolar platinum recording electrodes. A bipolar platinum stimulating electrode was placed on the soleus nerve near its entry into the muscle and supramaximal pulses lasting 0.1 ms were applied every 2.5 s. When appropriate, tetanic stimulations of 400 Hz for 10 s were applied every 5 min. The following materials were injected into the popliteal artery: N^6-2′-O-dibutyryl-adenosine-3′, 5′-monophosphoric acid, cyclic (db cyclic AMP), sodium fluoride (NaF), lanthanum chloride ($LaCl_3$), tetrodotoxin (TTX) and verapamil (a gift from Knoll laboratories). Each compound was dissolved in 0.85% NaCl solution so that 0.1 ml contained the amount to be administered per kg.

Forty injections of verapamil (0.001–200 μg kg^{-1}) were administered to seven animals. Doses lower than 0.01 μg kg^{-1} had no effect on the SBR induced by db cyclic AMP but 0.1 μg kg^{-1} depressed it in all seven preparations (Fig. 1). It completely prevented the production of SBR in five of these and reduced the duration of repetitive activity and the total number of repetitive potentials in the others (8 ± 15% (s.e.) and 6±3% of control, respectively). The administration of higher doses (up to 200 μg kg^{-1}) did not increase the effect of depression; it was impossible to prevent SBR completely in all fibres. Verapamil (0.1 μg kg^{-1}) also reduced the potentiation of muscle force caused by the transmission of the neural SBR to the muscle (20±4% of control) (Fig 1). In addition, verapamil reduced the brief bursts of action potentials in the motor axons and the rapid asynchronous action potentials and contractions in the muscle which were induced by the administration of db cyclic AMP to preparations in which the stimulator was turned off (drug-induced activity, DIA). Recovery from verapamil occurred within 5–15 min.

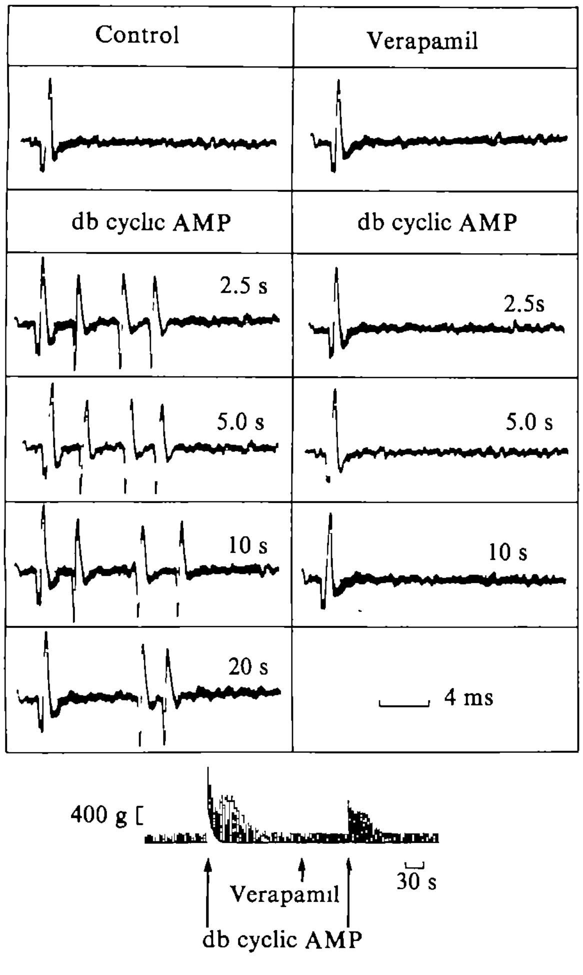

Fig. 1 Top, effect of verapamil on SBR produced in a soleus motor axon by db cyclic AMP. On the left, the first trace shows the response to a single stimulus applied before either drug; subsequent traces show the responses to similar stimuli applied once every 2.5 s after the intra-arterial administration of db cyclic AMP (200 μg kg^{-1}). On the right, the first trace shows the response of a single stimulus applied after the intra-arterial administration of verapamil (0.1 μg kg^{-1}) and subsequent traces show the responses of similar stimuli to db cyclic AMP following verapamil administration. Bottom, effects of verapamil on the potentiation of soleus muscle force produced by db cyclic AMP. Left, response produced by db cyclic AMP (200 μg kg^{-1}) on a neurally-stimulated muscle. Right, response of the same preparation to db cyclic AMP after administration of verapamil (0.1 μg kg^{-1}).

The effects of verapamil on the responses to NaF (100 μg kg^{-1}) were the same as on those to db cyclic AMP. Verapamil (0.1 μg kg^{-1}) blocked SBR in six of eight preparations and significantly reduced the duration of repetitive activity and the total number of repetitive potentials in the others (15±10% and 17±11% of control, respectively). Verapamil also reduced the potentiation by NaF of indirectly evoked muscle contractions (15±6% of control) and diminished the DIA produced by the administration of NaF to unstimulated preparations.

Thirty-five injections of LaCl$_3$ (0.01–100 μg kg^{-1}) were administered to six animals. A dose of 0.01 μg kg^{-1} significantly prevented SBR produced by the administration of db cyclic AMP (200 μg kg^{-1}). It completely prevented the production of SBR in four of these and reduced the duration of repetitive activity and the total number of repetitive potentials in the others (17±9% and 15±8% of control, respectively). Administration of higher doses (up to 100 μg kg^{-1}) did not increase the degree of suppression; it was impossible to prevent SBR in all preparations. LaCl$_3$ (0.01 μg kg^{-1}) also significantly reduced the potentiation of muscle contraction produced by the administration of db cyclic AMP to indirectly-stimulated preparations and diminished DIA. Recovery from LaCl$_3$ occurred within 5–15 min.

The effects of LaCl$_3$ on the responses to NaF (100 μg kg^{-1}) were also the same as on those to db cyclic AMP. LaCl$_3$ (0.01 μg kg^{-1}) blocked SBR in five of seven preparations (Fig. 2) and significantly reduced the duration of SBR and the total number of repetitive potentials in the others (20±12% and 21±12% of control, respectively). LaCl$_3$ also reduced the potentiation of indirectly evoked muscle contractions induced by NaF (37±6% of control) (Fig. 2) and diminished DIA.

Tetrodotoxin (0.01 μg kg^{-1}) was administered to five animals. This dose significantly depressed the repetitive neural activity which follows high frequency stimulation (post-tetanic repetition, PTR); the duration of PTR and the total number of post-tetanic repetitive potentials were reduced to 48±6% and 45±6% of control, respectively and also reduced the potentiation of muscle force caused by the transmission of the neural PTR to the muscle (64±4% of control (Fig. 3). In some cases, this dose of TTX also impaired neuromuscular transmission. Since the generation of PTR is thought to be related to sodium accumulation in the nerve during high frequency stimulation, its reduction by TTX was expected[8-10]. At 0.01 μg kg^{-1}, however, TTX did not significantly alter either the duration of SBR or the total number of repetitive potentials produced by the administration of db cyclic AMP (200 μg kg^{-1}) (121±14% and 103±12% of control, respectively) (Fig. 3). Similarly, the SBR produced by NaF (100 μg kg^{-1}) was unaffected by the administration of TTX; neither the duration of SBR (97±13% of control) nor the number of repetitive potentials (96±7% of control) was changed.

Stimulus-bound repetitive activity is thought to occur when the negative after-potential of the nerve terminal is prolonged for a period longer than the refractory period of the proximal portion of the axon. In this condition, the nerve terminal can act as a current sink for the proximal portion of the axon and re-excite it, thus giving rise to repetitive activity[9,10]. These considerations previously led us to suggest that db cyclic AMP and NaF prolong the after-negativity of action potentials in motor nerve terminals[1-3].

Since cyclic nucleotides have been shown to facilitate the influx of both sodium and calcium into cells[11-14], either ion could account for the SBR observed after the administration db cyclic AMP or NaF. The finding that doses of TTX adequate to reduce the sodium-related PTR did not alter the SBR produced by effects of db cyclic AMP or NaF suggests that sodium flux is not responsible for this latter phenomenon. Its sensitivity to the calcium antagonists lanthanum and verapamil, however, suggests that the SBR which accompanies the administration of db cyclic AMP or NaF is mediated by a calcium current.

Since a prolongation of the negative after-potential of the nerve terminal is implicit in this explanation for the generation of repetitive activity by db cyclic AMP and NaF, there are several mechanisms by which calcium influx would serve this end. With regard to a direct mechanism, the influx of calcium is known to carry a late depolarising current in nerves[15] and prolongation of this current by cyclic AMP could directly affect the afternegativity of the nerve terminal. An indirect mechanism is also possible since it has been shown that inward calcium currents activate late potassium conductance in neurones and that this calcium-dependent potassium conductance produces an after-hyperpolarisation[16-18]. Hyperpolarisation of the nerve terminal can set up conditions wherein the negative after-potential of the invading action potential is prolonged enough to generate SBR[19]. This possibility is given further support by reports that theophylline potentiates the after-hyperpolarisation in bullfrog sympathetic ganglia and that this effect is abolished by the removal of extracellular calcium[20].

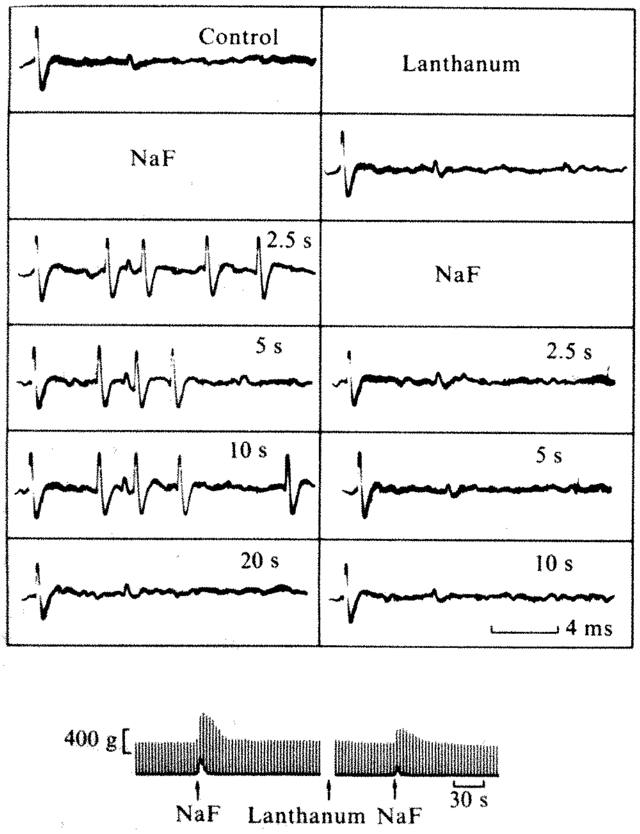

Fig. 2 Top, effect of lanthanum chloride on SBR produced in a soleus motor axon by NaF. Left, first trace is the response to a single stimulus applied before either drug; subsequent traces show the responses to similar stimuli applied once every 2.5 s after the intra-arterial administration of NaF (100 μg kg^{-1}). Right, fiirst trace is the response to a single stimulus applied after lanthanum chloride administration (0.01 μg kg^{-1}); subsequent traces show the responses to NaF following the administration. Bottom, effects of lanthanum chloride on the potentiation soleus muscle force produced by NaF. Left, response produced by the administration of NaF (100 μg kg^{-1}) to neurally-stimulated muscle. Right, response to NaF after the administration of lanthanum (0.01 μg kg^{-1}).

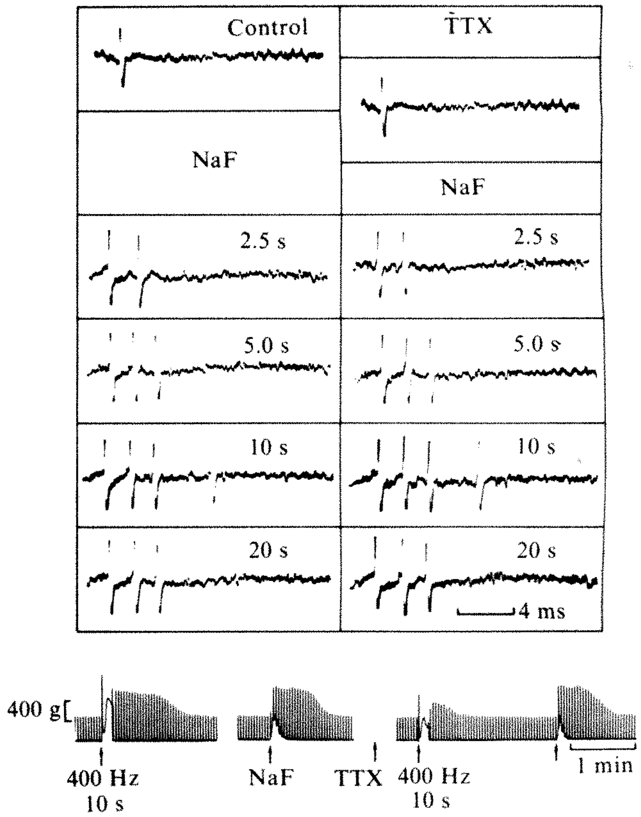

Fig. 3 Top, Effect of TTX on the SBR produced in a soleus motor axon by the administration of db cyclic AMP. On the left, the first trace shows the response to a single stimulus applied before either drug. Subsequent traces show the responses to similar stimuli applied at the noted intervals after the administration of db cyclic AMP (200 μg kg^{-1}). On the right, the first trace shows the response to a single stimulus applied after the intra-arterial administration of TTX; subsequent traces show the responses to db cyclic AMR following the administration of TTX. Bottom, Effects of TTX on PTR and the potentiation of soleus muscle force produced by db cyclic AMP. Left, Responses produced by high frequency stimulation (400 Hz for 10 s) and by administration of db cyclic AMP (200 μg kg^{-1} intra-arterially). Right, Response of the same preparation to high frequency stimulation and db cyclic AMP after administration of TTX (0.01 μg kg^{-1}).

The conclusion that intraneuronal cyclic AMP induces an influx of calcium is also of interest because an influx of calcium into nerve endings is known not only to carry a depolarising current and increase potassium conductance, but also to trigger the release of transmitter[21]. This suggests that cyclic nucleotides might be important in transmitter release.

In summary, our observations indicate that db cyclic AMP and related reagents produce repetitive activity in motor axons by promoting the influx of calcium into the motor nerve terminal and suggest that a cyclic nucleotide system may be part of the mechanism that regulates calcium flux into motor nerve terminals.

A modifier of $(Na^+ + K^+)$ ATPase in commercial ATP

WHEN most $(Na^+ + K^+)$ATPase preparations are allowed to hydrolyse ATP in the presence of different concentrations of Na^+ and K^+ ions, but with the sum $[Na^+]$ plus $[K^+]$ held constant, the behaviour observed is similar to that shown in the dotted curve of Fig. 1. K^+ ions activate at low concentrations, and inhibit (by competing with Na^+ ions at intracellular sites) at high concentrations. There is a broad plateau in the middle of the curve. We reported[1] recently that $(Na^+ + K^+)$ATPase from the outer medulla of pig kidney showed behaviour of a different kind, like that shown in the solid curve of Fig. 1. Here, K^+ ions apparently inhibit even at relatively low concentrations, so that, as the activating effect of K^+ ions approaches saturation, the inhibitory effect becomes predominant and causes a sharp fall to an intermediate level of activity. This effect was more pronounced at 20 or 30 °C than at 37 °C, and at *p*H 7.5 than at *p*H 6.5. We have now discovered that this peculiar behaviour depends on the use of Sigma 'Sigma grade' ATP, and is not seen with Boehringer ATP (see Fig. 1). We report here that many samples of 'Sigma grade' ATP contain something which reacts with $(Na^+ + K^+)$ATPase reversibly and with a high affinity, making the enzyme much more sensitive to inhibition by K^+ ions. The changed response to K^+ ions, and the sensitivity of this response to *p*H can account for the inhibition of kidney $(Na^+ + K^+)$ATPase by 'Sigma grade' ATP reported by Charney, Silva and Epstein[2], and the altered *p*H optimum reported by Katz and Michell[3].

Evidence that it is the Sigma 'Sigma grade' ATP that carries the modifying agent comes from experiments of two kinds. First an experiment like that of Fig. 1 but using an equimolar mixture of Sigma 'Sigma grade' and Boehringer ATP gave the Sigma pattern. Since the modifier must have been present in the mixture, it is evidently the Sigma pattern that represents the behaviour of the modified enzyme. An alternative approach, using mixtures of Sigma and Boehringer ATP in different proportions, is illustrated in Fig. 2. Here the total ATP concentration was held constant at 3 mM or 6 mM, $[Na^+]$ and $[K^+]$ were fixed at 130 mM and 20 mM respectively, and $[Mg^{2+}]$ was equal to the total ATP concentration. It is important to note that 3 mM ATP was sufficient to saturate the enzyme. The results show that, in these conditions, the activity was highly sensitive to the level of Sigma ATP but was scarcely affected by the level of Boehringer ATP. This implies (1) that it is the Sigma 'Sigma grade' ATP that carries the modifier, and (2) that the modifier is not competitive with ATP. Separate experiments (not shown) indicate that the inhibition by Sigma 'Sigma grade' ATP is reversible and is not affected by changes in the enzyme concentration. The results in Fig. 2 may therefore be used to calculate a 'K_i' for Sigma 'Sigma grade' ATP, which works out as 2.18 mM from the data at 3 mM total ATP and 2.39 mM from the data at 6 mM total ATP. If the modifier is present at a molar concentration of, say, 1% of the Sigma ATP, its K_i must be about 23 μM. The figure of 1% is, of course, entirely arbitrary, but it is clear that, on any likely assumptions, the affinity of the modifier for the enzyme must be high.

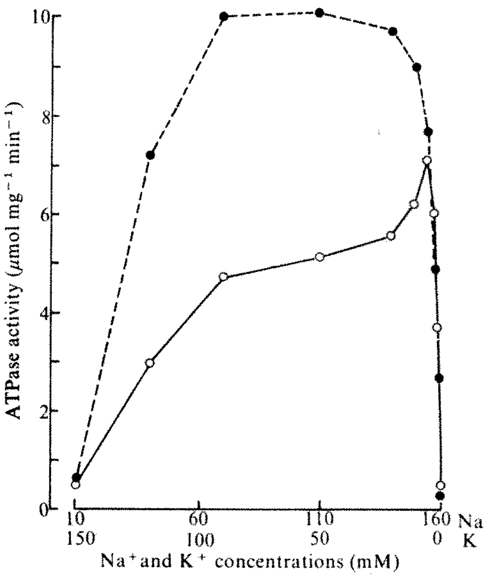

Fig. 1 Rate of ATP hydrolysis as a function of Na^+ and K^+ concentrations. $(Na^+ + K^+)$ATPase prepared from the outer medulla of pig kidney by the simpler method of Jørgensen[6] was incubated at 37 °C for 20 min in a medium containing 2.5 mM ATP, 2.5 mM $MgCl_2$, 30 mM histidine (*p*H 7.5), 0.1 mM EGTA, and NaCl and KCl to give the concentrations shown on the abscissa. The amount of ATP hydrolysed by the end of the incubation did not exceed 10% of the total. The rate of hydrolysis for each set of conditions was estimated from the orthophosphate released after 20 min, as preliminary experiments showed that deviations from linearity during this period could be neglected. ●, Boehringer ATP; ○, 'Sigma grade' ATP.

The most obvious questions raised by these findings are: what is the modifier, and, since Sigma 'Sigma grade' ATP is extracted from horse muscle, does it have a physiological role? The modifier has been present in most, but not all, samples of Sigma 'Sigma grade' ATP that we have used over the past year, and is not restricted to a single lot number. So far we have not succeeded in separating the modifier from the ATP. Passing Sigma 'Sigma grade' ATP down a cation exchange column in the H^+ form did not alter its subsequent behaviour, so that if the modifier is a cation it must be very tightly bound to the ATP. When the ATP was adsorbed on to a column of Dowex 1 resin in the Cl^- form, the modifier was not eluted by a volume of 20 mM NH_4Cl–20 mM HCl sufficient to elute most of the contaminating ADP, but was eluted along with ATP by 250 mM HCl. Clearly, more sophisticated chromatography is necessary. An alternative approach to identifying the modifier is to think of possible candidates and add them individually to 3 mM Boehringer ATP. GTP, CTP, UTP, deoxyATP, adenosine tetraphosphate, 2,3-diphosphoglycerate, fructose 1,6-diphosphate and Ca^{2+} ions have been tested in this way, but none gave the Sigma pattern.

Another interesting question is: what does the modifier do to the enzyme that changes its response to K^+ ions so dramatically? Inhibition by K^+ ions at low concentrations is a feature of the peculiar $(Na^+ + K^+)$ATPase found in low-potassium ungulate red cells, and in these cells the K^+ ions

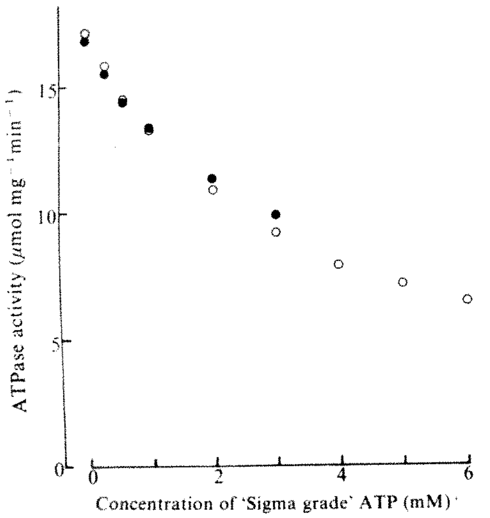

Fig. 2 The effect of substituting Sigma 'Sigma grade' ATP for Boehringer ATP on the rate of ATP hydrolysis by $(Na^+ + K^+)$-ATPase from pig kidney outer medulla. The enzyme was incubated for 20 min at 37 °C in a medium containing 3mM (●) or 6 mM ATP (○), $MgCl_2$ equimolar with the ATP, 20mM KCl, 130 mM NaCl, 30 mM histidine (*p*H 7.5) and 0.1 mM EGTA.

act intracellularly[4]. With kidney $(Na^+ + K^+)$ATPase it is not possible to tell at which surface of the membrane the K^+ ions act. We hope to resolve this problem by using resealed human red cell ghosts, for we have found that the human red cell $(Na^+ + K^+)$ATPase behaves like the solid curve of Fig. 1 when hydrolysis of Sigma 'Sigma grade' ATP containing the modifier is allowed to occur at subnormal temperatures. It is also intriguing that the effect of the modifier on the kidney $(Na^+ + K^+)$ATPase is entirely prevented if the enzyme is first incubated with trypsin in the absence of K^+ ions, until the rapid phase of inactivation (see ref. 5) is complete. The residual enzymatic activity behaves like the dotted curve in Fig. 1 whether Sigma 'Sigma grade' ATP or Boehringer ATP is used (ref. 1 and unpublished).

The molecular mechanisms of anaesthesia

IT is generally accepted that neutral anaesthetics, such as the *n*-alkanols and *n*-alkanes, act from a hydrophobic site[1]. Discussion has tended to focus on the nature of this site and, particularly, whether it is located in a membrane protein or in the interior of a bilayer[2,3]. If the site is in a bilayer then the question arises as to how the proteins involved in nervous impulse propagation are affected. We present here new evidence concerning the anaesthetic properties of the *n*-alkanes which points to the bilayer as the site of action and also suggests a mechanism for the inhibition of impulse propagation. Briefly, the cut-off in anaesthetic potency on ascending the homologous series is found to be closely related to the decrease in adsorption of the alkane into a cholesterol-containing bilayer. In addition, the anaesthetic hydrocarbons produce a concentration-dependent increase in bilayer thickness. On the basis of these two observations, and from our knowledge of the properties of the ion channel-forming polypeptide gramicidin A (ref. 4) we propose that a thickening of the bilayer regions of the nerve membrane by the alkanes destabilises the open ionic channels formed during electrical excitation.

Several factors make the *n*-alkanes of particular interest in the study of anaesthesia. First, they do not have multiple functional groups which would complicate analyses of their interactions. Second, their interactions with bilayers are relatively well understood from their use as solvents in the formation of black lipid films[5]. Finally, they constitute a homologous series in which there is a hitherto unexplained loss in anaesthetic potency of the higher members[1,6]. This cut-off effect was first revealed by the experiments of Führner[7,8] on general anaesthesia in mice and has been confirmed by Mullins, who showed that mice are unaffected by *n*-decane even after prolonged exposure[6]. We have investigated the ability of *n*-alkanes to block the propagation of the nervous impulse in isolated nerve preparations. Figure 1 shows that *n*-pentane and *n*-hexane cause rapid blockage of the action potential in both squid giant axons and in frog sciatic nerve. Although the information is not strictly required for present purposes, voltage-clamp experiments (to be described elsewhere) show that both the sodium and, to a lesser extent, the potassium currents are reduced by the alkane. For short exposure times and incomplete suppression of the action potential, the blockages were normally reversible. *n*-Nonane and *n*-decane have no significant effect in either preparation. These results are not accounted for by low solubilities and long diffusion times. The new data show, therefore, that as in whole animals, there is a marked decline in anaesthetic potency with increasing chain length in the *n*-alkanes between pentane and nonane.

The adsorption of *n*-alkanes into a lipid bilayer can be measured using black film techniques[5,15]. The bilayers are formed so as to be in equilibrium with solutions of the alkane under examination. Measurements of the electrical capacity per unit area yield the thickness of the hydrocarbon region of the bilayer and, since the areas per molecule of the lipids (for example, phospholipid and cholesterol) present are, at most, weakly dependent on the alkanes used, changes in capacity reflect changes in alkane adsorption. Previous studies have demonstrated an effect of chain length on adsorption, but only for molecules larger than *n*-decane[9]. But, these results were obtained for bilayers which did not contain cholesterol. Analyses of nerve membranes indicate that their cholesterol–phospholipid ratio is approximately 1:3 (ref. 10) and consequently the alkane adsorption experiments were repeated with bilayers of composition comparable with this. Figure 2 shows that the chain length dependence of adsorption is now between *n*-pentane and *n*-decane and, from the thicknesses, it can be concluded that for homologues larger than decane there is very little alkane in the bilayer[9].

The close correlation between the decline in impulse blocking potency and the decrease in bilayer adsorption for the *n*-alkanes, revealed by Figs 1 and 2, would not have been predicted from the bulk phase partition coefficients as in the Meyer–Overton hypothesis[1], and constitutes a simple, if superficial, explanation for the chain length cut-off effect. Moreover, since it is known that the *n*-alkanes accumulate primarily in the centre of a bilayer[11], the correlation reinforces the idea that it is from this position that they exert their anaesthetic action. It is, of course, quite possible that hydrophobic binding sites in membrane proteins may exhibit a size discrimination similar to that of the lecithin–cholesterol bilayer but, until this is demonstrated, the protein site hypothesis is not the simplest available. In a non-equilibrium system it could be argued that even if the protein itself were the site of action and showed no chain length discrimination, a cut-off effect might still be seen if access to the protein were through the lipid bilayer. But, the experimental evidence outlined earlier does not support the notion that the chain length cut-off is a non-equilibrium effect. Hence the route which the anaesthetic might take to a target does not have to be considered.

It may be significant that a similar chain length dependence exists for both impulse blockage within an axon and for general anaesthesia by the alkanes. Thus, even though it seems likely that different proteins are involved in these two processes, they would need to have comparable alkane binding properties. While this is quite conceivable, it is simpler for the moment to invoke the ubiquity of the lipid bilayer.

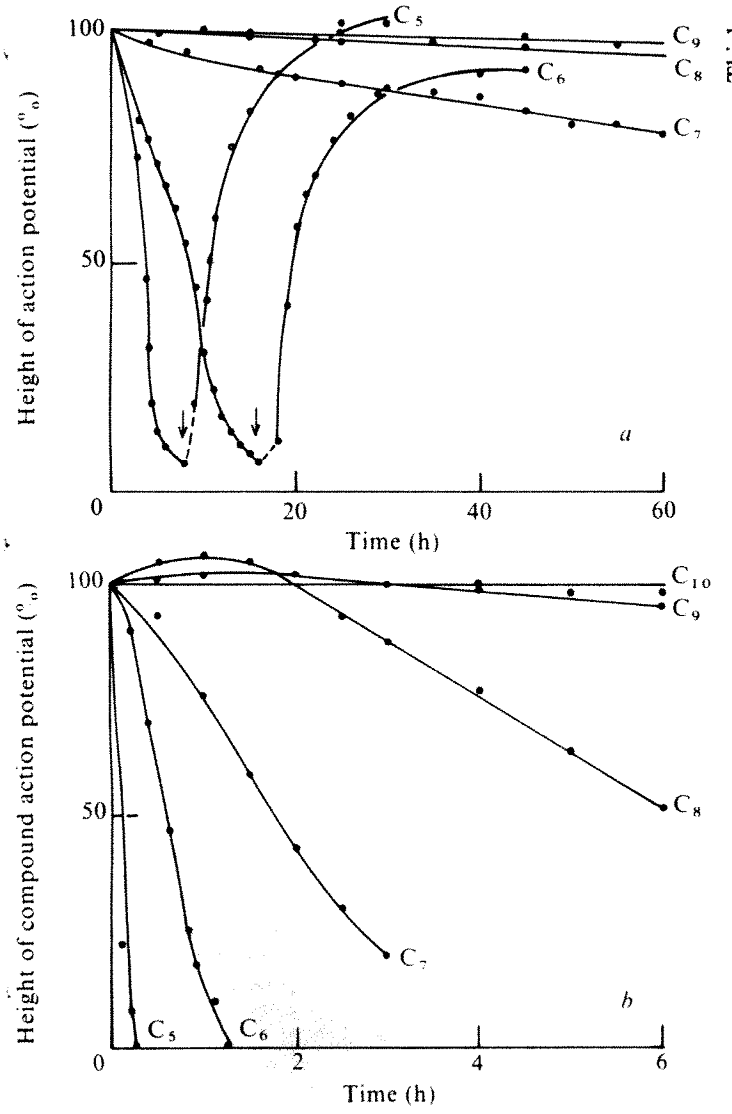

Fig. 1 Nerve impulse blockage by the *n*-alkanes from *n*-pentane (C_5) to *n*-decane (C_{10}). *a*, The propagated action potential of the squid giant axon (from *Dorytheutis plei*) monitored as the chamber was perfused with saturated solutions of the alkanes in artificial seawater. Vertical arrows indicate a switch to alkane-free seawater. Flow rates were approximately 10 ml min^{-1}; internal recording was with a 0.5 M KCl-filled glass capillary; the temperature was 18 °C. The effect of the alkanes on the resting potential of the axon was small and variable. *b*, The compound action potential of the desheathed frog sciatic nerve from *R. temporaria*. Dilute emulsions of alkanes in frog Ringer were used to ensure an adequate supply of material; saturated solutions became depleted by a large uptake into the nerve bundle. Perfusion rates were about 1.5 ml min^{-1}. The nerve was stimulated at 6 Hz and monophasic compound action potentials were recorded from a platinum electrode situated at the end of the nerve. The temperature was 18–21 °C.

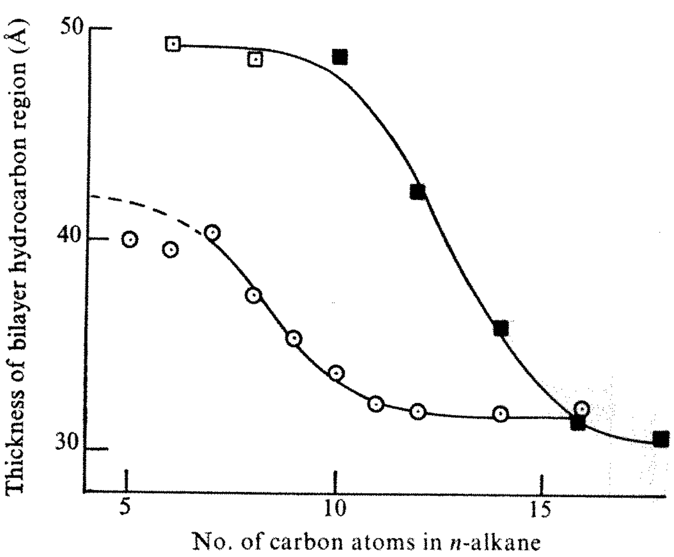

Fig. 2 The variation in hydrocarbon layer thickness of black lipid films formed in equilibrium with different *n*-alkanes. ⊙, Egg phosphatidylcholine–cholesterol (~ 2.5:1) films; the bulk lipid solution was 7 mM phospholipid and 21 mM cholesterol. The pentane and hexane results are possibly low owing to the difficulty of preventing evaporation of these volatile solvents. ⊡, ■, Cholesterol-free egg phosphatidylcholine films. (■, data of ref. 9). The aqueous phase was 0.1 M NaCl and the temperature was 20 °C. In each experiment the lipids were dissolved in the appropriate alkane and the aqueous solution was equilibrated with the lipid solution before the start of the experiment.

The supposition that nerve impulse blockage originates in a lipid bilayer raises the question of exactly how the mechanisms of ion movement involved in electrical excitability might be affected. Recent evidence concerning the unit conductances of ion channels in excitable tissues[12-14] supports the notion that these channels consist of pore-like structures. In view of this, it is of interest to consider how the functioning of a relatively well-characterised polypeptide pore, such as gramicidin A, is affected by modification of its bilayer environment. It is known that the conductance of a black lipid film containing gramicidin decreases rapidly as the thickness and hydrocarbon content of the film increases[4,15]. This arises from a lowering of the stability of the open channels. Since bilayer thickness is increased by the *n*-alkanes (Fig. 2) these observations may have some relevance to anaesthesia. An empirical relationship for the constant K of equilibrium between open and closed gramicidin channels in a black lipid film can be written in the form

$$K \approx A \exp(-h/B)$$

where h is the thickness of the membrane and is considered to take values only larger than or equal to the length of the gramicidin channel. A is a constant, and B, for the particular system and range of h concerned, is 2.2 Å (ref. 15). This equation is consistent with the proposal that a dimpling of the lipid is required for the functioning of a pore in a membrane of thickness greater than the pore length (Fig. 3). The dimpling involves an increase in the surface area of the bilayer and hence requires an investment of energy proportional to the surface tension. On the basis of this crude model, therefore, the free energy of the open pore should be roughly proportional to the bilayer thickness, so giving the observed exponential form of the above equation. In addition, the value of the bilayer tension which corresponds to $B = 2.2$ Å is approximately 3 mN m^{-1}, in good agreement with experiment[9,16].

Provided that the *n*-alkanes increase the thickness of bilayer

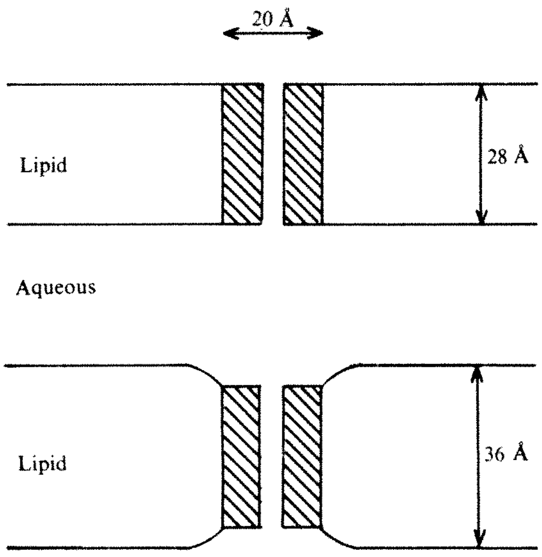

Fig. 3 The thickness–tension model. The shaded region represents a gramicidin channel situated in a lipid bilayer. In the top diagram the bilayer is of thickness equal to the channel length. In the lower diagram the bilayer thickness has been chosen to correspond with the concentration of pentane (about 90% saturated) sufficient to suppress completely the action potential in the nerve axon. The deformation or dimpling of the bilayer in the lower diagram involves a surface free energy change which tends to reduce the stability of the open channel.

regions surrounding the ion channels in excitable membranes, then the type of mechanism proposed for gramicidin could obviously apply also to impulse blockage. Whether or not the channels in an axon are of dimensions comparable with those shown in Fig. 3 is of no great importance for the general argument. Thus, if a channel is normally in equilibrium with the surrounding membrane, a thickness change in the lipid is almost certain to stress the channel and hence destabilise it. While there is no conclusive evidence that the *n*-alkanes do thicken biological membranes, there are strong indications that this is so. First, measurements of the adsorption of *n*-alkanes into erythrocyte membranes have given results which are very similar in both their chain length dependence and in their absolute values to the data of Fig. 2 for cholesterol-containing bilayers (F. Dagger and D.A.H., in preparation). Second, preliminary experiments on the squid giant axon at its normal resting potential, suggest that its capacity per unit area, measured at 1 kHz and with 1 mV applied, decreases by about 15% in pentane-saturated artificial seawater (D.A.H., J. Kimura and B. Urban, unpublished). Circumstantial evidence therefore supports the proposed thickness-tension link between the perturbation of bilayer structure by the alkanes and their anaesthetic potency.

There are no compelling reasons for believing that all anaesthetics share a common mechanism, but it seems possible that the bilayer thickness-tension model outlined above may apply to some more polar anaesthetics. For example, a cut-off in potency with increasing molecular size occurs for the *n*-alkanols[17] and for the barbiturates[18], implying that they also may act through thickening of a bilayer. Furthermore, ethanol and diethyl ether at anaesthetic concentrations both lower the capacity per unit area of black films and therefore must increase the film thickness. Finally, the reversal of anaesthesia by the application of pressure, which has been reported for a range of systems, is thought to take place through the restoration of a hydrophobic region, expanded by the anaesthetic, to its original dimensions[19]. If this is so, it is consistent with the idea of membrane thickness changes and with the existence of a common mechanism for a variety of molecules.

After submitting this paper we learnt of a paper by R. G. Ashcroft, H. G. L. Coster and J. R. Smith (*Nature*, in the press) in which it was reported that benzyl alcohol caused a thickening of lipid bilayers, and in which it was suggested that this effect might be instrumental in inhibiting sodium channel conductance.

Membrane asymmetry and blood coagulation

ALTHOUGH there is compelling evidence that membrane components are non-randomly distributed between the two surfaces, the physiological significance of membrane asymmetry has so far remained obscure. Since the exterior surface of blood cell membranes is presumably devoid of negatively charged phospholipids which have a regulatory role in blood clotting, a possible function of lipid asymmetry in the coagulation process can be anticipated. We describe here experiments devised to show that the asymmetric distribution of membrane phospholipids in blood cells may serve a biological purpose, by contributing to maintain the delicate balance between regulating haemostasis and avoiding thrombosis.

The main function of phospholipids in blood coagulation is to provide a catalytic surface on which various coagulation factors interact, thus increasing their local concentrations. For example, the final lipid-activated step in the coagulation process is the conversion of prothrombin into thrombin by the prothrombinase complex, which requires at least four components in addition to prothrombin, the proteins factor X_a, and factor V_a, Ca^{2+} and phospholipids[1]. Of these components, only factor X_a is able to convert prothrombin into thrombin by limited proteolysis[1–5], but its individual action is considerably slower than with the complete prothrombinase complex[6].

In situ, the platelet plasma membrane presumably provides the phospholipid–water interface (platelet factor 3), which is required to accelerate the coagulation process[7]. It has been shown[8–10] that the clot-promoting activity of phospholipids *in vitro* is not attributable to a certain phospholipid class, but to a specific negative charge of the phospholipid surface. In particular, negatively charged phospholipids such as phosphatidylserine and phosphatidylglycerol (when properly diluted with neutral phospholipids like lecithin or phosphatidyl ethanolamine) exhibit maximal activation of the coagulation-process[11,12].

It is generally accepted that membranes are highly asymmetric structures both with respect to their proteins and their lipids (see refs 13–16 for recent reviews). We have shown that the non-random distribution of phospholipids between the interior and the exterior half of the platelet plasma membrane is similar to that of the erythrocyte membrane[17]. In both membranes, phosphatidylserine is apparently nearly exclusively located on the cytoplasmic surface, whereas the outer monolayer of the membrane consists of neutral phospholipids, particularly sphingomyelin. The other two major phospholipid classes, lecithin and phosphatidylethanolamine, are present on both membrane sides though not to the same extent. We report here on the possible implications of blood cell membrane asymmetry for the coagulation process. Since methods are readily available to prepare different types of sealed and non-sealed erythrocyte ghosts, this type of membrane has been used in the present study rather than the platelet surface membrane which is more difficult to manipulate.

Blood from healthy volunteers was collected in 0.13 M sodium citrate (9 ml blood + 1 ml citrate). Red cells, non-sealed ghosts and resealed right-side out ghosts were prepared as described previously[18]. Inside-out sealed ghost vesicles were prepared according to Steck[19]. The coagulant activity of these preparations was determined by its ability to shorten the clotting time on recalcification of 'normal' human platelet-poor plasma in the presence of Russell's viper venom (legend to Fig. 1). For the presentation of the coagulant activity of membranes and lipids we report directly the clotting times rather than attempt to convert these to some arbitrary units of activity. It is realised that such clotting times are a complex function of lipid activity, but no real advantage is gained by using conventional log–log calibration curves obtained by serial dilution of plasma. In view of the wide range of the final membrane phospholipid concentration, the values on the abscissa are plotted logarithmically.

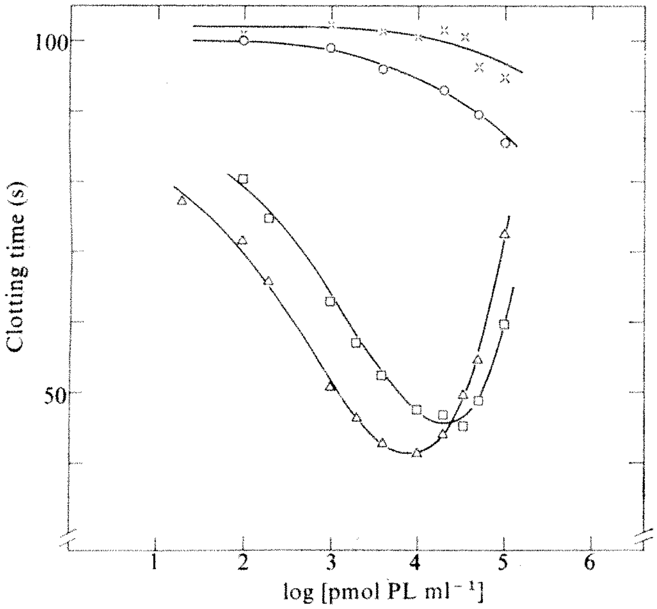

Fig. 1 Effect of in- and outside of erythrocyte membranes on clotting time of plasma. Assay: 0.1 ml of citrated plasma (centrifuged 10 min, 5000*g*) was incubated at 37 °C for 30 s with 12 ng of Russell's viper venom (which gives a blank coagulation time of 100 s on recalcification), followed by addition of 0.1 ml of various dilutions of red cells or ghosts and 0.1 ml 25 mM $CaCl_2$. A stopwatch was started simultaneously with the addition of $CaCl_2$. The time required for the formation of a firm fibrin clot was determined by the arrest of a rotating metal wire (2 mm length, cut from a regular paper clip), driven by a magnetic stirrer. This method gives the same clotting times as observed by using a Kolle hook, but the standard deviations are smaller and usually below 1%. PL, phospholipid added as red cells or ghosts. ×, Erythrocytes; ○, resealed ghosts; △, inside-out vesicles; □ non-sealed ghosts.

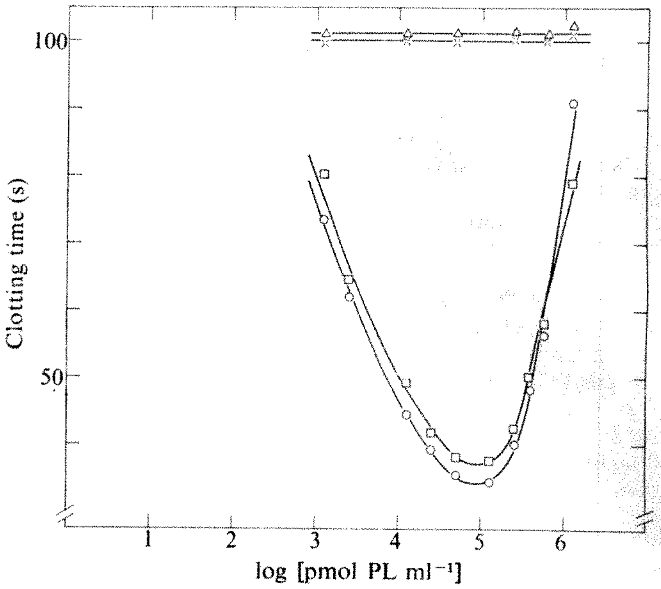

Fig. 2 Effect of liposomes on clotting time of plasma. Liposomes simulate inner and outer half of red cell and platelet plasma membranes. ×, Platelet surface membrane outer phospholipids; □, platelet surface membrane inner phospholipids; △, red cell membrane outer phospholipids; ○, red cell membrane inner phospholipids. For phospholipid compositions see Table 1. Assay conditions as for Fig. 1. PL, phospholipid added as liposomes.

When only the outside of the erythrocyte membrane is exposed (either intact cells or resealed ghosts) no significant reduction of the blank clotting time is observed over a wide range of concentration (Fig. 1). On the other hand, when either the membrane interior (inside-out vesicles) or both membrane sides (non-sealed ghosts) are exposed, a two- to threefold reduction of the coagulation time is observed at optimal concentrations. At higher ghost concentrations, clotting times increase; this is consistent with the view that excess of lipid will result in a dilution of coagulation factors at the lipid surface[20]. The results suggest that only the phospholipids at the membrane interior have procoagulant activity, also since inside-out ghost vesicles are slightly more active that non-sealed ghosts.

This hypothesis was further investigated by testing liposomes with the same phospholipid composition as present in the outer half and inner half of human red cell membranes and pig platelet plasma membranes (Table 1). Handshaken liposomes (4 µmol phospholipid per ml of 0.9% (w/v) NaCl) were used

Table 1 Mole ratios of phospholipid in liposomes simulating outer and inner half of red cell and platelet plasma membranes

	Red cell membrane		Platelet plasma membrane	
	Outer half	Inner half	Outer half	Inner half
PC	44	15	26	34
Sph	44	10	52	4
PE	12	47	20	28
PS	0	28	2	34

Data calculated from refs 17 and 21. PC, phosphatidylcholine prepared from egg yolk[22]; Sph, sphingomyelin prepared from bovine brain[23]; PE, phosphatidylethanolamine prepared from egg yolk[22]; PS, phosphatidylserine prepared from pig brain[24].

rather than sonicated vesicles, to avoid artifically-induced phospholipid asymmetry which is known to occur in mixed vesicles as a result of charge differences and packing properties[25]. It should be noted, however, that with multilamellar liposomes only 10–15% of the lipids are available at the outer surface[26]. As shown in Fig. 2, liposomes having the same phospholipid composition as present in the outer membrane half of either red cell membranes or platelet plasma membranes do not reduce whatever the blank clotting time. On the other hand, liposomes with the same phospholipid composition as the inner half of red cell or platelet plasma membranes produce a threefold reduction of the coagulation time at optimal concentrations. The amount of lipid required is higher than with ghosts, since only a fraction of the total lipid is available at the surface of handshaken liposomes.

It is realised that the measured procoagulant activity of the lipids is not performed at one particular transitory stage of the blood clotting process, in spite of the presence of Russell's viper venom which is known to activate both factor *X* and factor *V* (ref. 27). Nevertheless, the results strongly suggest that the outer surface of blood cells is devoid of phospholipids which are active in blood coagulation, mainly due to the absence of any significant amount of phosphatidylserine. This phospholipid comprises about 30% of the phospholipids at the membrane interior, representing a concentration which has been shown to be optimal in activating prothrombin by the prothrombinase complex[11].

The presence of procoagulant phospholipids only at cytoplasmic surfaces of blood cells is not only consistent with phospholipid asymmetry in membranes, but might also represent an important mechanism both in avoiding thrombosis and in regulating haemostasis. It could be judged as potentially dangerous to have procoagulant phospholipids at the outer surface of blood cells, which may bring about a 'permanent' condition of hypercoagulability. This fact itself could provide a physiological reason for an asymmetric phospholipid distribution in blood cell membranes. On the other hand, after disruption of the vessel wall the sequence of platelet adhesion, release reaction and ADP-induced platelet aggregation, presumably accounts for the primary arrest of bleeding. Provided that platelet factor 3 activity becomes accessable during this process, its availability should come after the release reaction since no phosphatidylserine can be labelled from the outside during the release reaction[28]. Moreover, it has been demonstrated that only a small fraction of lipid procoagulant activity becomes available during release reaction as compared with the activity obtained upon lysis[29,30]. This raises the question whether during or after formation of the primary haemostatic platelet plug, either (partial) lysis of platelets or an as yet unknown mechanism which translocates phosphatidylserine through the plasma membrane is necessary to provide a catalytic lipid surface for interacting coagulation factors.

Ion transport and rotation of bacterial flagella

BACTERIA swim by rotating their flagella[1–4]. A flagellum consists of a thin helical filament which is joined by a hook to a rod and a set of rings embedded in the cell wall and the plasma membrane[5,6]. Gram-positive bacteria such as *Bacillus subtilis* have two rings, one of them, the M ring, binding to the plasma membrane and the other, the S ring, being located on the outside of the membrane. Gram-negative bacteria such as *Escherichia coli* have two additional rings which are associated with the peptidoglycan layer and the outer lipopolysaccharide membrane. The energy source of the flagellar motor seems to be not ATP itself but rather an intermediate in oxidative phosphorylation which is interpreted as an electrochemical potential gradient for hydrogen ions across the plasma membrane[7–9]. Berg[3,4] has proposed that the rotation of the flagellum is driven by the translocation of ions down an electrochemical gradient. This hypothesis, however, has never been formulated in terms of a specific model. An entirely different mechanism based on hydrodynamic interactions between plasma membrane and basal body of the flagellum has been suggested by Adam[10]. Here, we examine Berg's hypothesis more closely and propose a model for the electromechanical coupling between ion flow and flagellar rotation.

Following Berg[4] we assume that the S ring is attached to the peptidoglycan layer of the cell wall and that the M ring, which is mounted rigidly on the rod, is able to rotate in the plasma membrane (Fig. 1). We further assume that hydrogen ions which have in the extracellular medium a high electrochemical potential with respect to the cytoplasm[11–13] are able to flow through the interstice between the S and M rings and through the periphery of the M ring to the cytoplasm, as shown in Fig. 1. How can this flow of ions generate a torque?

According to current concepts, the passage of ions through cellular membranes takes place within localised structures termed ion channels. An ion channel may consist of a series of polar ligand groups which partly replace the primary hydration shell surrounding the ion in water. In this way the channel offers to the ion an energetically favourable pathway through the hydrophobic interior of the membrane. A well studied example is the gramicidin channel[14–16], which is selective for univalent cations and in which the permeating ion interacts with the carbonyl oxygens of amide groups. In the following we shall assume that the face of the S ring, which is in contact with the M ring, contains radially arranged rows of ligand groups (Fig. 2). If the opposite contact face of the M ring contains similar rows of ligand groups, but arranged in a nonradial direction, the two sets of rows intersect at a certain angle. Evidence for a ring structure with non-radial arrangement

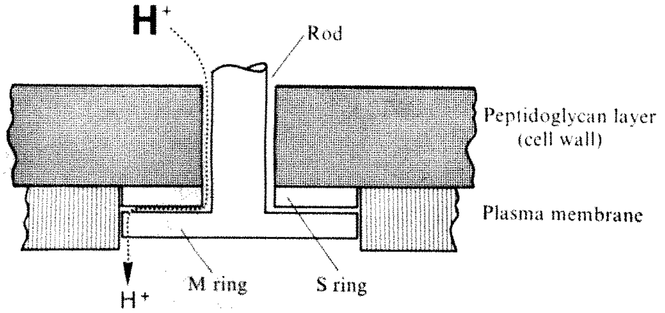

Fig. 1 Structure of the basal body of the flagellum of Gram-positive bacteria, according to De Pamphilis and Adler[5] and to Berg[4]. The S ring is attached to the cell wall and the M ring, which is mounted rigidly on the rod, is able to rotate in the plasma membrane. Hydrogen ions are assumed to flow down an electrochemical gradient from the outside through the interstice between S and M ring and through the periphery of the M ring to the cytoplasm.

of subunits has been obtained by De Pamphilis and Adler[5] in their electron microscopic studies of bacterial flagella, although it was not possible to assign the observed non-radial ring structure to one specific type of ring (M, S, P or L).

Figure 2 shows that, when the S ring is held fixed and the M ring is rotated, the points of intersection move radially with respect to the S ring. We further assumed that the energy of interaction of the ion with one ligand row is not sufficient to compensate for the energy required to remove the ion from water but that an energetically favourable state is reached if the ion is located at the site of intersection where it has twice as many ligand groups available. In these circumstances the ion is constrained to move together with the site of intersection. In the model depicted in Figs 1 and 2, part of the electrochemical gradient of H^+ drops across the rings in a radial direction so that an ion located between the S and M rings experiences a radial (centrifugal) force. As we have assumed that ions are confined to the intersection sites between the two sets of rows, an ion movement down the radial potential gradient results in a rotation of the M ring with respect to the S ring. In this way, ions entering the ring system near the axis and leaving it at the periphery, drive the rotation of the flagellum in a manner not unlike the action of a turbine.

If K is the radial force acting on the ion and θ the angle between the two intersecting ligand rows (Fig. 2), the torque exerted by an ion on the M ring is equal to $(a/2)K \sin 2\theta$, where a is the distance of the intersection point to the centre. The difference in electrochemical potential of H^+ between cytoplasm and extracellular space may be expressed as $e_0\Delta\psi_{eq}$ where e_0 is the charge of the proton and $\Delta\psi_{eq} = \Delta\psi - (59 \text{ mV}) \Delta pH$ is the equivalent electrical potential difference ($\Delta\psi$ is the membrane potential). If the fraction α of $\Delta\psi_{eq}$ acts across the width $(R_2 - R_1)$ of the rings (R_1 and R_2 are the inner and the outer diameter of the rings, respectively) and if the turbine contains on the average n hydrogen ions, then the mean torque M (averaged over one repetition period) is given by

$$M = \alpha B n e_0 \Delta\psi_{eq}$$

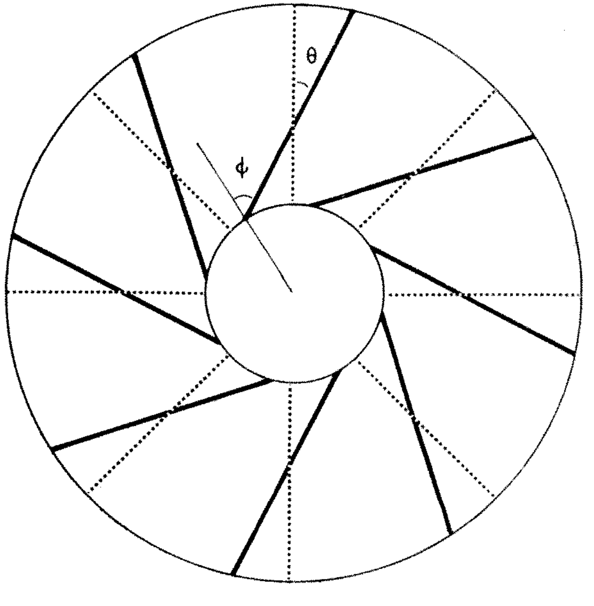
where B is a dimensionless quantity which depends on the geometry of the ligand system. It may be shown that for the model represented in Fig. 2 the relation $B = \rho \sin^2\psi/(\varphi - \text{arc sin} (\rho \sin\varphi))$ holds, where $\rho = R_1/R_2$ and φ is the tilt angle of the non-radial ligand row (Fig. 2). From the structural data of the basal body[5] a value of $\rho \simeq 0.3$ is obtained. If the tilt angle is chosen to be $\varphi = 60°$, one finds that $B \simeq 0.3$. Numerous attempts have been made to determine the electrochemical gradient for H^+ across the bacterial plasma membrane, and there is now considerable evidence that in respiring bacteria $\Delta\psi_{eq}$ is of the order of 0.1–0.2 V (cytoplasmatic side negative)[11–13]. Using these values of $\Delta\psi_{eq}$ and B, and assuming, for the purpose of an estimate to the order of magnitude, $\alpha \simeq 1$ and $n \simeq 10$, one obtains a torque of $M \simeq 10^{-19} J$. This figure may be compared with the actual torque generated by the flagellar motor. From a hydrodynamic analysis of flagellar motion, Coakley and Holwill[17] estimated that the power dissipation of a single flagellum rotating at a frequency of 50 Hz is about $P = 4 \times 10^{-17}$ W. This corresponds to a torque $M = P/\Omega$ of $1.3 \times 10^{-19} J$ (Ω is the angular velocity). Similar values of M were obtained from experiments with tethered bacteria described by Silverman and Simon[2] and by Berg[3]. Thus, the mechanism considered above is able to generate a torque of the required order of magnitude. The predicted torque M is independent of angular velocity Ω and the external load which means that $\Omega = M/f$ should decrease when the friction coefficient f is increased. This is consistent with the experimental findings of Berg[3] who observed that the rotational frequency of tethered cells was approximately inversely proportional to the viscosity of the external medium (see also Schneider and Doetsch[24]).

The number of ions flowing through the turbine in one second may be estimated to be $P/e_0\Delta\psi_{eq} \simeq 4 \times 10^{-17}/1.6 \times 10^{-19} \times 0.2 \simeq 10^3$ (an estimate of 10^3 ions per cycle has been given by Berg[3] for a tethered cell spinning at 10 Hz). If the number ν of ligand rows on each ring is assumed to be identical with the number of subunits found in the electron microscopic study of De Pamphilis and Adler[5] ($\nu = 16$), the rate of ion flow along one row is of the order of 100 s^{-1}. If a single row contains about 10 ion-binding sites then the required jump rate of the ion between adjacent sites is $\sim 10^3 \text{s}^{-1}$. This value is well within the range of feasible jump rates in ion channels[18].

In recent years, it has become clear that bacterial chemotaxis is based on the ability of bacteria to reverse the direction of rotation of their flagella in response to sensory stimuli[19,20]. A reversal of the direction of rotation could occur by a conformational transition of the subunits of the M ring[10], which would change the tilt angle of the ligand rows from φ to $-\varphi$ (Fig. 2). Such a conformational transition could be triggered by a transient change in membrane potential[21–23].

Several modifications of the proposed model are conceivable. Other ion species besides H^+ which have a non-equilibrium distribution across the cytoplasmatic membrane may drive the flagellar motor. Furthermore, the geometry of the ligand rows depicted in Fig. 2 is certainly not optimal and many other

Fig. 2 Hypothetical arrangement of ligand groups on the S and M rings. Ligand rows on the S (dashed) and M rings (full lines) are superimposed. When the M ring is rotated the points of intersection, which are assumed to be ion-binding sites, move radially with respected to the S ring.



arrangements are feasible. Another (less likely) alternative would consist in assuming that the torque is generated between the rod and the bushing in the cell wall, the rod being equipped with straight axial and the bush with helical ligand rows (or vice versa).

I thank Winfried Boos and Gerold Adam for interesting discussions.

Analysis of positional information applied to cirral patterns of the ciliate *Euplotes*

IN studying the relative positions of structural features on the surfaces of organisms, most biologists are content with qualitative impressions of pattern. This approach is inadequate when there are large variations among individuals, as occurs in the taxonomically important positional patterns formed by the locomotory organelles, the cirri, of the hypotrich ciliate genus *Euplotes*. The frequency distribution of all intercirral distances provides a quantitative measure of cirral pattern that incorporates individual variations. A comparative study[1] among different *Euplotes* populations of such distributions reveals a small set of basic cirral patterns. It also demonstrates that certain cirral patterns may be simulated by morphogenetically plausible alterations in others, thus supporting the hypothesis that certain cirral patterns are derivative of others. The theoretical creation of artificial positional patterns that mimic naturally occurring patterns provides a useful perspective on the systematics of this group of organisms.

The ventral surface of *Euplotes* (Fig. 1) bears a system of morphogenetically unified landmarks, the frontoventral and transverse cirri, which arise during asexual division from subpellicular kinetosomal plaques. These compound ciliary organelles develop from the simultaneous elongation and condensation of a series of five anteroposterior kinetosomal streaks[2]. The posterior portions give rise to the five transverse cirri found universally throughout the genus. Anteriorly, at most two additional cirri develop from each streak, forming the frontoventral cirri. It is the number and relative positions of cirri along the streaks that determine the cirral pattern. In most of the 51 recognised species[3], there are 10 frontoventral cirri, as in *E. harpa* (Fig. 1), with a 'cirrotype' of 10. But some species are of lesser cirrotype, with several common freshwater forms being of cirrotype 9, and a few marine species of cirrotypes 8 and 7.

A simple measure of cirral pattern is obtained by calculating, for each specimen of a sample, from coordinate data for the positions of the frontoventral and transverse cirri (including the buccal cirrus), all intercirral distances. These distances are scaled by a factor external to the cirral system proper, the length of the specimen. For any given population ($n \geqslant 25$) of *Euplotes*, regardless of cirrotype or mean size, the frequency distribution of such relative intercirral distances provides a measure of the cirral pattern of that population. The distributional profiles of different populations then may be compared using the maximum difference ($D_{\max}$) between their cumulative frequency distributions, that is, the Kolmogorov–Smirnov statistic[4].

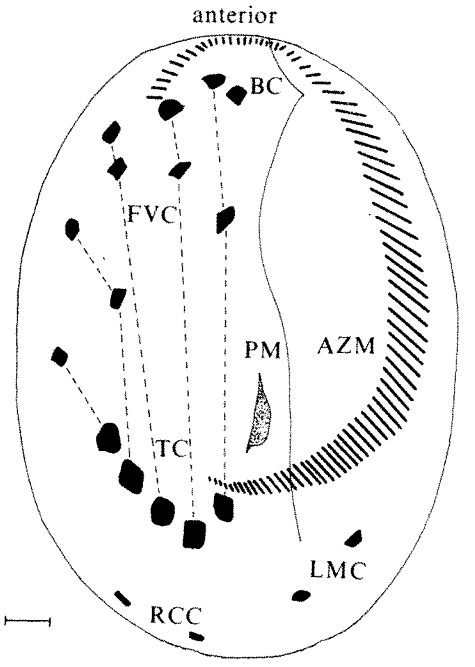

Fig. 1 Schematic diagram of the ventral surface of a silver-stained specimen of *E. harpa*, a brackish-water species with cirrotype 10, illustrating the basal plaques of the frontoventral (FVC) and transverse (TC) cirri as well as the longitudinal subpellicular streaks (dashed lines) from which these cirri arise during morphogenesis. Also illustrated are the buccal cirrus (BC), which is treated as part of the preceding system; the adoral zone of compound ciliary membranelles (AZM) that line the mouth; the right caudal cirri (RCC); the left marginal cirri (LMC), and the paroral membrane (PM). The line scale indicates 10 μm.

To assess the extent of inherent variability in cirral patterns, 17 subclonal populations of the largest species in the genus, the brackish-water form *E. harpa*, were grown in different conditions of temperature and salinity during 3 yr. Samples of at least 50 specimens were selected from each population. All specimens were selected randomly from preparations silver-stained by the Chatton–Lwoff procedure[5], except that only non-reorganising, well impregnated and properly oriented specimens in micronuclear interphase[6] were chosen. Figure 2 shows the relative frequency distributions for the two most dissimilar samples from these populations, all of which were derived from the same original individual. For these two distributions, $D_{\max}$ is 0.0693, and this value provides a conservative criterion for judging the similarities of other distributions. If two samples of, for example, different species differ in their distributions by less than the difference that can exist among subclones of *E. harpa*, it would be unwise to consider their cirral patterns to be different.

By this criterion, many of the numerous species of *Euplotes* have indistinguishable cirral patterns[1]. Most cirrotype 10 patterns are very similar, with only two of 13 geographically disparate samples differing slightly from the common pattern (Fig. 1). Indeed, for each cirrotype known to exist within the genus, at most two cirral patterns exist, as judged by comparisons of the distributions of 33 clonal samples of diverse origin. The internal integrity of each of these few patterns permits the following interpretation of cirral pattern diversity within the genus.

There are only two ways in which a *Euplotes* may possess a cirrotype of 9. The first, as in *E. patella*, involves the absence of a cirrus at the position in which the third cirrus (numbering from posterior to anterior) in the fourth streak (numbering from the organism's left to right), cirrus 3/IV, occurs in *Euplotes* of cirrotype 10. The second variant, as in *E. affinis*, occurs as a result of the absence of the 2/IV cirral position. That is, there are only two cirri in streak IV in forms of cirrotype 9. In the more common variant, the second cirrus occurs at the anterior end of the streak, while in the rarer variant, it occurs in the middle. Results of a distributional analysis based on 16 samples confirm the existence of these two distinct patterns[7] and indicate that the latter variant is the more homogeneous cirral pattern; nonetheless, the more common pattern is not more variable than the subclones of *E. harpa*.

The integrity of each of the above cirral patterns suggests that the cirral patterns of forms with cirrotypes less than 10 can be explained by a simple loss of cirri (either by the direct depletion of kinetosomal numbers in the affected streaks or by the redistribution during morphogenesis of unchanged numbers of kinetosomes). To test this hypothesis, several artificial distributions were constructed by the recalculation of intercirral distance distributions after the removal of the coordinate data for appropriate cirri from samples of *Euplotes* of cirrotype 10. Then these were compared with the distributions of forms with cirral 'deficiencies' presumed to be homologous with the artificial forms.

Figure 3 illustrates the distributions for two freshwater samples of *Euplotes* of cirrotype 9 with the *affinis*-type cirral pattern and the artificial distribution obtained subsequent to the removal of cirrus 2/IV from a freshwater sample of *Euplotes* of cirrotype 10. The fit is remarkably good ($D_{max} = 0.0424$) and well within the range of variation of subclones of *E. harpa*. An adequate fit ($D_{max} = 0.0612$) to a *patella*-type cirral pattern was also obtained from this sample after the deletion of cirrus 3/IV. Similarly, reasonable simulations of both cirrotype 8 and both cirrotype 7 patterns were obtained using artificial distributions derived from the small marine species *E. minuta* (Fig. 4).

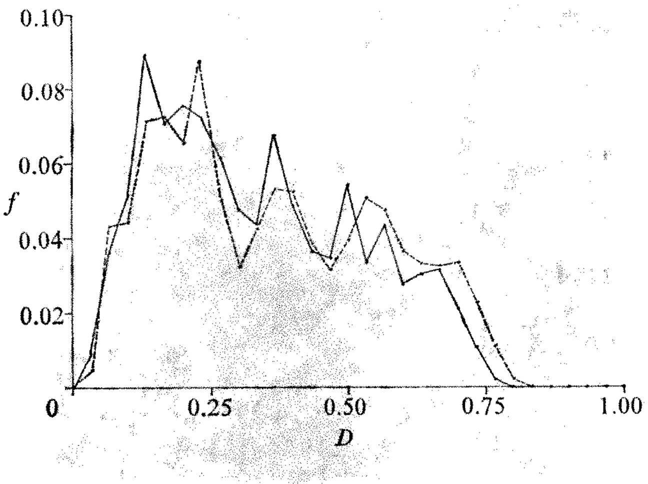

Fig. 2 Relative frequency (f) distributions of scaled intercirral distances (D) for the two most dissimilar ($D_{max} = 0.0693$) of 17 *E. harpa* subclones, based on samples of 57 (dashed line) and 55 (solid line) specimens. Coordinate data for each specimen were obtained by placing a Leitz Ortholux microscope with drawing tube on top of an electronic two-dimensional digitiser. Data were recorded on cassette tape, transferred to nine-track magnetic tape, and thence to on-line disk storage for processing on an IBM 370-165-II computer system, using a Fortran program written by me. For each of the 2,122 specimens, the coordinate data were visually checked by inspection of computer plots. Intercirral distances and their distributions were calculated from the coordinate data, Gould plots were made, and comparisons among distributions were performed automatically.

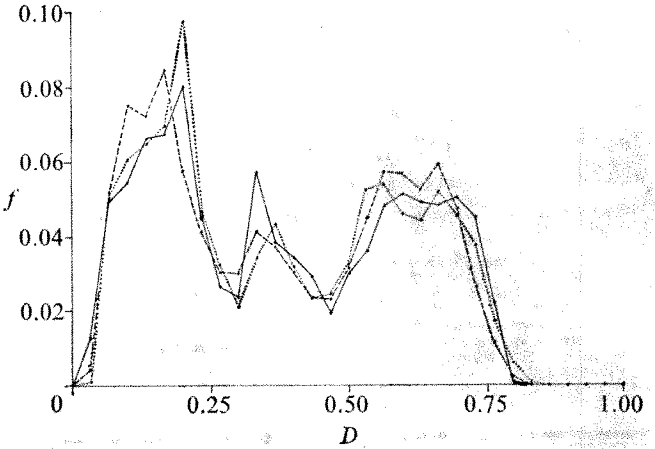

Fig. 3 Relative frequency distributions for two samples of *Euplotes* with cirrotype 8: *E. affinis* from Stevenage, Hertfordshire, UK (dashed line), and from Toronto, Ontario, Canada (dotted line); and an artificial *affinis*-type sample (solid line) created from a sample of *Euplotes* with cirrotype 10 from Inuvik, Northwest Territories, Canada, by the removal of the coordinate data for two cirri.

These results demonstrate the plausibility of explaining certain cirral patterns as derivative from others. In conjunction with quantitative studies of variation in other taxonomic features[8], it is possible to suggest a phylogeny for the genus *Euplotes* that eschews untested typological dichotomies[1].

The analysis of positional data by means of the distributions of interpositional distance is an approach to biological pattern analysis that has obvious applications. Not only may it be applied to the systematics of other hypotrich genera, in which cirri exist in fixed patterns, and to, for example, setal positions in various insects, but it also may be used to study the changes in positional relationships that occur during development in various taxa. It may be possible to show, for example, that certain patterns are arrested stages in the development of others, as is undoubtedly the case with some of the oxytrichid hypotrichs[9] among the ciliated protozoa.

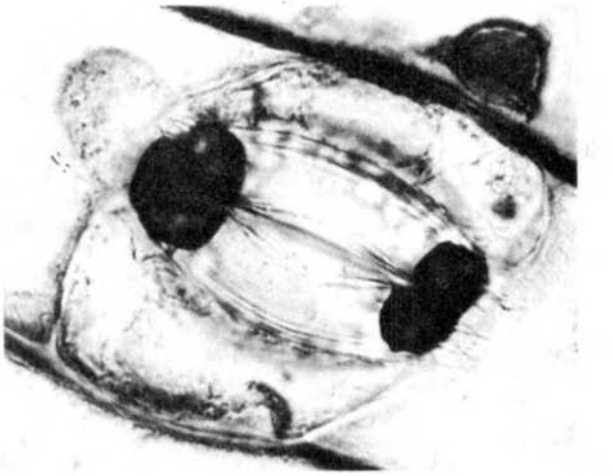
Ion-adsorbent substomatal structures in *Tradescantia pallidus*

STOMATAL movements result from turgor imbalances occurring within the stomatal complex which are largely brought about by differential potassium distribution between the guard cells and adjacent epidermal cells[1-4]. The guard cell vacuole has been established as the sink of the potassium flux during stomatal opening[5,6], but the source of the ions has not been identified. It is generally believed that the ion flux is apoplastic because plasmodesmata have only occasionally been observed between the guard and adjacent epidermal cells[7-9]. We have described substomatal ion-adsorbent sites in some species of filicopsid ferns and Commelinaceae which we believe could act as the immediate sink/source of potassium ions involved in stomatal closing and opening[11]. Discrete accumulations of Macallum's stain for potassium[12] were demonstrated at both poles of the guard cell complex on the face adjacent to the mesophyll. These sites corresponded to substomatal endocuticular swellings observed by scanning electron microscopy which, when collapsed, revealed the presence of a disk-shaped structure on the outer face of the guard cell walls at the site of ion adsorption. Direct observation of the ion-adsorbent sites was prevented by the overlying endocuticular substomatal sacs. We have now observed these sites directly in *Tradescantia pallidus* and obtained evidence which strongly implicates them in stomatal functioning.

Tradescantia pallidus was selected as a more suitable material for further investigations into the form and function of substomatal ion-adsorbent sites because its stomata respond readily to physiological experimentation and it has well developed ion-adsorbent sites, as determined by the Macallum technique[11] (Fig. 1). Segments of fresh whole leaves were mounted lengthwise on a scanning electron microscope stub and cut longitudinally, along the longitudinal axes of the stomata, immediately before being plunged into liquid nitrogen. The specimen was then mounted and observed on the cryostage of a JSM-35 scanning electron microscope in an uncoated condition.

Fig. 1 Stomatal complex of *Tradescantia pallidus* stained for potassium showing the polar accumulations (× 1,000).



Our findings indicate that the ion-adsorbent sites in this species consist of discrete subtetrahedral bodies lying in the intercellular space between the pole of the guard cell and the adjacent polar subsidiary cell (Fig. 2*a*). The ion-adsorbent bodies are closely paired so that each pole of each guard cell is associated with its own single body. While one face of the ion-adsorbent body is adpressed onto the subsidiary cell wall, there seem to be no direct connections between the body and the protoplasts of either the guard or subsidiary cells. Each body has an approximate volume of 0.28×10^{-15} m^3 in comparison

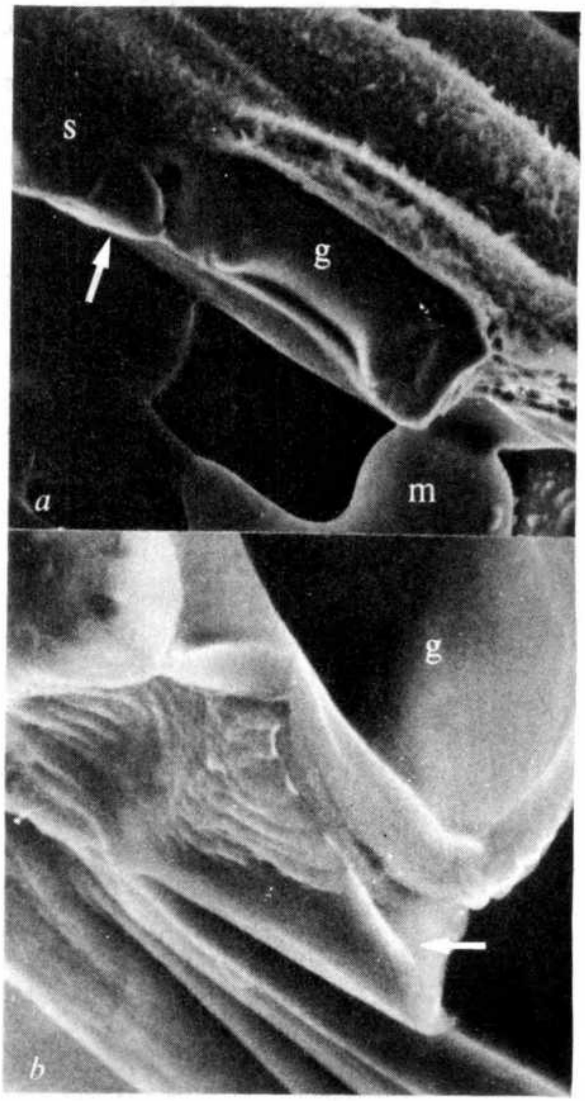


Fig. 2 *a*, Scanning electron micrograph of a vertical longitudinal section through the lower epidermis of *Tradescantia pallidus*. The section passed exactly through the centre of a stomatal complex leaving a single guard cell (g) and polar subsidiary cell (s). The mesophyll tissue (m) indicates the orientation of the section. An ion-adsorbent body (arrowed) can be seen in the intercellular space between the pole of the guard cell and the adjacent subsidiary cell (× 1,000). *b*, Scanning electron micrograph of a vertical section through the polar region of a guard cell (g) of *Tradescantia pallidus*. The internal paradermal wall of the guard cell has laminate structure with free spaces (arrowed) lying between successive layers (× 5,000).

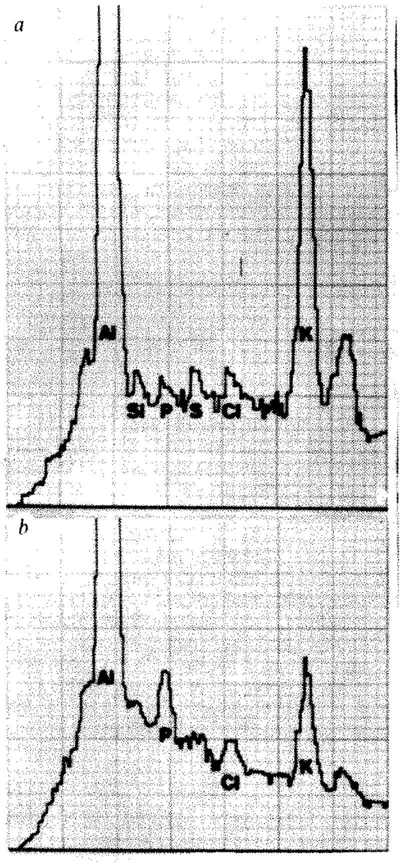

Fig. 3 Preliminary electron microprobe analyses of the stomatal complex of *Tradescantia pallidus*. The probe was about 6 µm in diameter at an accelerating voltage of 18 keV for 100 s. The peak to the immediate right of the potassium peak in the spectra is of a composite nature in that it is made up of potassium K_{β} and calcium K_{α} emissions. *a*, K_{α} spectral emission from the ion-adsorbent body illustrated in Fig. 2*a*; *b*, K_{α} spectral emission from the polar region of the adjacent guard cell illustrated in Fig. 2*a*.

with the guard cell lumen volume of about 7.85×10^{-15} m^3; the combined volumes of a pair of ion-adsorbent bodies associated with a single guard cell, is, therefore, in the order of 7% of the guard cell volume.

When viewed from the side adjacent to the mesophyll, the bodies can be seen to be covered by the endocuticle, which is strongly plicated at the pole of the guard cell and over the immediately adjacent areas of the polar subsidiary cells, the bodies are similar to the trabeculae reported on from the stomata of *Polypodium vulgare*[10]. Sections through the polar region of the guard cells indicate that the extracellular space, in which the ion-adsorbent bodies are located, is contiguous with spaces present in the matrix of the lower paradermal wall of the guard cell (Fig. 2*b*). These spaces are not apparent in thin sections observed under the transmission electron microscope (probably as a result of fixation procedures), although the differentially-thickened cell wall in this region seems to be strongly laminate.

Electron microprobe analysis of the ion-adsorbent body (Fig. 3*a*) suggests that it is particularly rich in potassium compared with the protoplast at the pole of the adjoining guard cell (Fig. 3*b*). In addition, the body also contains appreciable quantities of silicon, sulphur, phosphorus and chlorine, while only the latter two are detectable in comparable amounts in the guard cell protoplast.

Our findings conform to the hypothetical arrangement proposed for the substomatal structures as found in *Polypodium vulgare*[10]. The ion-adsorbent bodies are situated in an extracellular position in both species studied, although their exact location differs. The bodies are in close association with the outer face of the lower paradermal cell walls at the poles of the guard cell complex in *Polypodium vulgare*, while in *Tradescantia pallidus* they are situated in the intercellular space between the pole of the guard cell complex and the polar subsidiary cells.

Potassium is the most important cation involved in the stomatal mechanism and the considerable concentrations of the ion detected in the ion-adsorbent bodies must strongly implicate their involvement in stomatal movements. Being situated as they are at the end of the epidermal water pathway[12], the bodies are in a strategic position to adsorb potassium, among other ions, from the transpiration stream. The bodies can thus have a dual role. They maintain a store of bound potassium which can be released, as and when required, for incorporation into the guard cell vacuole. At the same time, they remove other potentially toxic ions from the transpiration stream (our unpublished data) which could otherwise become lodged elsewhere in the apoplast, and possibly be taken up in the symplast, as water leaves the tissues at the evaporative sites around the stomata.

The scanning electron microscopy was carried out at JEOL (UK) Ltd, London, and we thank Mr E. Toulson for technical assistance.

Heterogeneous population of mitochondrial DNA molecules in higher plants

THE physicochemical properties of mitochondrial (mt)-DNA of higher plants have been reported[1–4]. mt-DNAs occur as closed circles with molecular weights of $(60\text{–}70) \times 10^6$ and it is likely that each mitochondria contains several of these circles. mt-DNAs isolated from different higher plants exhibit similar physicochemical parameters: all mt-DNAs so far analysed[1–5] in higher plants band at a unique buoyant density of 1.706 g cm^{-3} in neutral CsCl gradients and the few published melting points and reassociation kinetics are not significantly different[2–4]. Not enough values have been reported to state on possible differences in the contour length measured by electron microscopy. Thus, mt-DNAs isolated from different higher plants cannot be specifically identified by conventional physicochemical techniques. We have recently reported that the analysis of restriction nuclease digests by gel electrophoresis provides a very sensitive test to identify specifically chloroplastic (cp)-DNAs isolated from different plant genera and species[6]. We show here that this technique also allows the characterisation and the specific identification of mt-DNAs isolated from various higher plants. We used *Eco*RI specific cleavage to evidence the general occurrence of heterogeneous population of mt-DNA molecules within an higher plant and to detect clear differences between mt-DNAs extracted from normal and cytoplasmic male-sterile wheat.

Etiolated seedlings of *Cucumis sativus* L. var. Vert long maraîcher, *Triticum aestivum* var. Capitole, *T. aestivum* var. Florence Aurore and *T. aestivum* var. Gaines (normal and male sterile lines) were used. *Solanum tuberosum* var. Bintje was grown as callus tissue[7]. Liquid cell suspensions of normal and

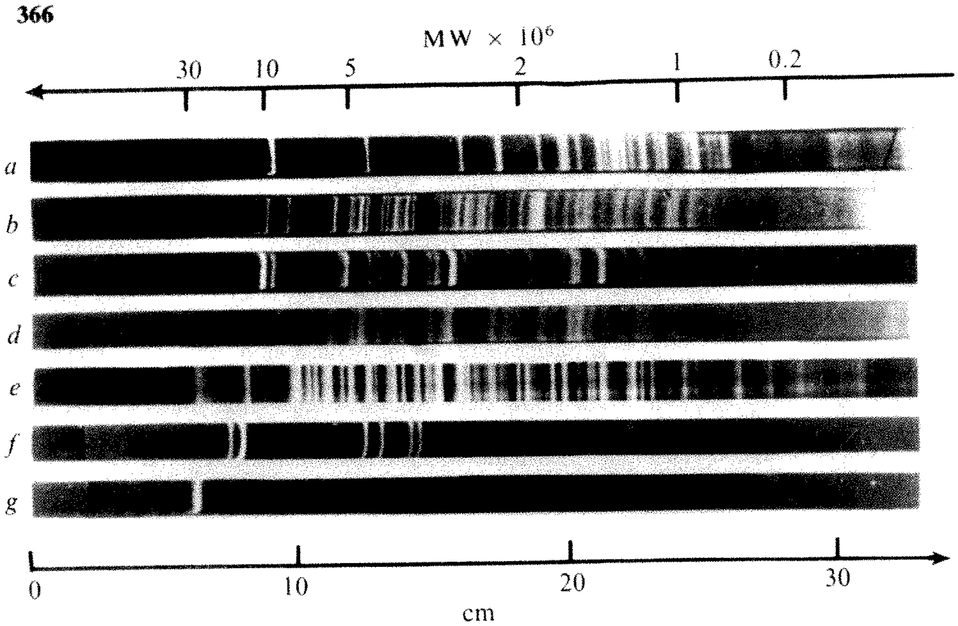

Fig. 1 Agarose slab gel electrophoresis of *Eoc*RI digests of mt-DNAs from: *b*, wheat (*T. aestivum* var. Capitole); *c*, potato; *d*, cucumber; *e*, virginia creeper. Wheat (*T. aestivum* var. Capitole) cp-DNA (*a*) and λ*plac*5 DNA (*f*) were used for comparison and molecular weight standards respectively. The arrow indicates the direction of migration. Homogenisation of plantlets (etiolated, 10-cm long, roots removed) was carried out with a Waring blender (3×5 s, maximum speed); calluses and liquid cultured cells were disrupted by a French press (3,000 p.s.i.) in buffer A (ref. 10). The homogenate was filtered through a 40-μm nylon net, centrifuged at 1,200*g* for 10 min and the supernatant spun at 15,000*g* for 15 min. The pellet was dispersed with a Potter homogeniser, recentrifuged at 1,200*g* and 15,000*g*, and dispersed again. A DNase treatment was achieved at 50 μg cm^{-3} (DNase I), 4 °C for 1 h and the DNase was removed by 2 washings in buffer B (ref. 10) at 15,000*g* for 15 min. The dispersed pellet was loaded on a 30–60% sucrose gradient in buffer B; after 1 h at 22,000 r.p.m. in an SW.25 II rotor, the mitochondrial band was recovered, diluted with buffer B and pelleted. DNA was isolated as described[6] for cp-DNA. The supercoiled DNA band was diluted with buffer C (ref. 10) and run at 35,000 r.p.m. overnight in an SW41 rotor. The pellet was suspended in 0.1 M NaCl, 10^{-2} M Tris, 10^{-3} M EDTA, *p*H 8 and the liquid was a cleared by a 30-s centrifugation at 20,000*g* (Eppendorf microcentrifuge); the drug was removed by chromatography on a Dowex 50 Na^+ column (20×4 mm). Purity and circularity were checked as for cp-DNA (ref. 6). *Eco*RI was purchased from Miles or prepared according to ref. 11. Experimental conditions for digestion, electrophoresis and ultraviolet fluorescence photography were as before[6], except that the 0.7% Agarose electrophoresis was achieved on 38-cm long, 15-cm wide (eight slots), 4-mm thick slab gels.

tumorous *Parthenocissus tricuspidata* L. were cultured in darkness[8] and collected during the exponential growth phase. Mitochondria were purified by two cycles of differential centrifugations and cleared from contaminating DNA by a DNase treatment. Mitochondria were freed from DNase by two washes and further purified by a sucrose gradient. The supercoiled mt-DNAs were isolated as the lower ultraviolet fluorescent band of propidium diiodide or ethidium bromide CsCl gradients[6] and made drug-free by a short Dowex chromatography. The purity was checked by analytical CsCl gradients (unimodal and sharp band at 1.706 g cm^{-3}) and the circularity was controlled by a Kleinschmidt spreading followed by positive staining with acid–alcoholic uranyl acetate[9]. The purified mt-DNAs were then digested by saturating amounts of *Eco*RI, *Bam*I or *Sal*I, and the digests analysed by electrophoresis on 38-cm long, 0.7% Agarose slab gels. *Eco*RI restriction fragments given by λ*plac* 5 DNA and by wheat cp-DNA were used as molecular weight standards. Gels were stained with ethidium bromide and ultraviolet fluorescence photographs were taken.

Figure 1 shows the electrophoretic pattern of the mt-DNAs extracted from cucumber, potato, wheat and virginia creeper. Some 50 distinct bands were resolved in each case, about 40 moved more slowly than the bromophenol blue. Like cp-DNA, the mt-DNA of a given plant seems to be characterised by a specific digestion pattern and may be easily distinguished from that of another plant belonging to a different genus. These patterns were found easily reproducible: several independent preparations of each mt-DNA were individually digested and lead to rigorously reproducible banding patterns, whatever the digestion time (3–12 h). The same number of bands was obtained on 58-cm Agarose gels in individual tubes.

mt-DNA isolated from three hexaploid wheats, *Triticum aestivum* var. Capitole, *T. aestivum* var. Florence Aurore and *T. aestivum* var. Gaines display an identical pattern (Fig. 2,

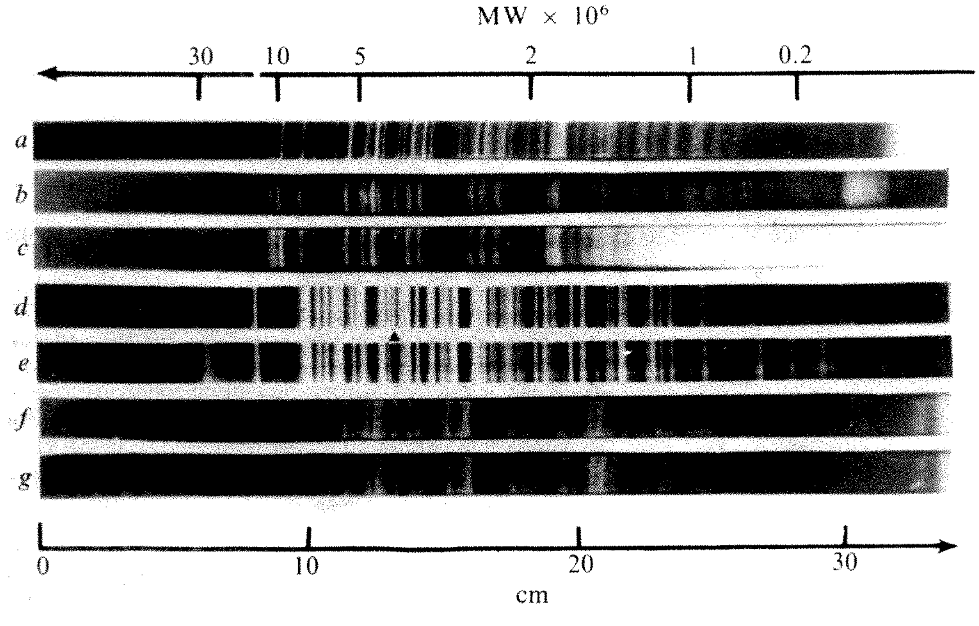

Fig 2 Agarose gel electrophoresis of *Eco*RI digests of mt-DNAs isolated from: *a*, *Triticum aestivum* var. Capitole; *b*, *T. aestivum* var. Florence Aurore; *c*, *T. aestivum* var. Gaines; *d*, liquid cultured normal cells of *Parthenocissus tricuspidata* L.; *e*, liquid cultured crown-gall cells of *P. tricuspidata* L.; *f*, cucumber hypocotyls; *g*, cucumber cotyledons. Isolation and anlaysis were performed as for Fig. 1.

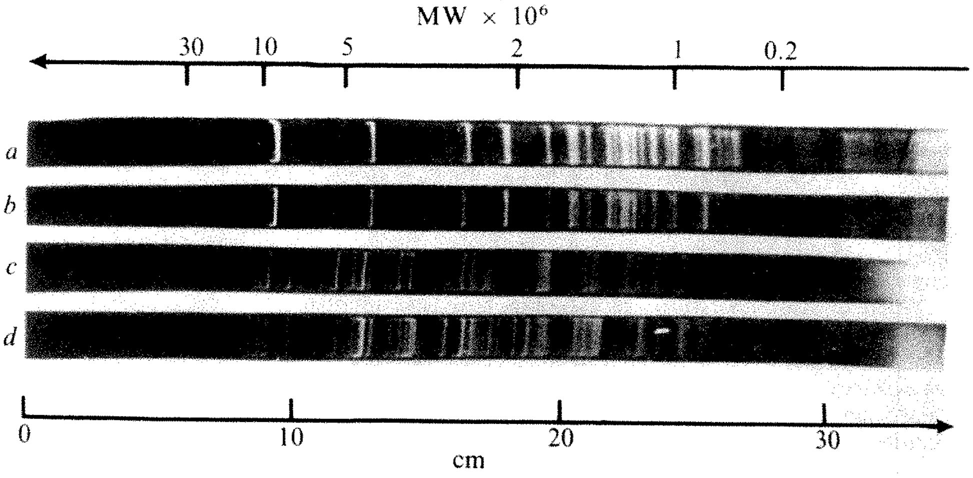

Fig. 3 Agarose gel electrophoresis of *Eco*RI digests of *a*, cp-DNA isolated from normal *T. aestivum* var. Gaines (cytoplasm *T. aestivum*); *b*, cp-DNA isolated from cytoplasmic male-sterile *T. aestivum* var. Gaines (cytoplasm *T. timophevii*); *c*, mt-DNA from normal *T. aestivum* var. Gaines; *d*, mt-DNA from cytoplasmic male-sterile *T. aestivum* var. Gaines. Isolation and analysis were performed as described in Fig. 1.

gels *a–c*); this identity is direct evidence for the isocytoplasmic origin of these varieties, deduced from interspecific reciprocal crosses[12]. The corresponding cp-DNAs also led to identical patterns (results not shown).

The sensitivity of this method is illustrated on Fig. 2, gels (*d*) and (*e*), where mt-DNAs extracted from normal and tumorous cell suspensions of virginia creeper differ only by one band among 50; whereas this difference is highly reproducible, it is not known however whether this DNA modification is related to the tumorous transformation or simply results from an *in-vitro* evolution of the strains. Gels (*f*) and (*g*) in Fig. 2 show that mt-DNAs extracted from two physiologically different organs, cotyledons and hypocotyls, of a given plant (cucumber) do not present any detectable difference.

The cytoplasmic male sterility which affects many higher plant species has been claimed to result from mutation(s) in chloroplastic and/or mitochondrial DNAs (ref. 13). The mt-DNAs have been isolated from normal *T. aestivum* var. Gaines (cytoplasm *T. aestivum*) and from cytoplasmic male sterile *T. aestivum* var. Gaines (cytoplasm *T. timophevii*). Figure 3 *c, d* shows that the male sterile mt-DNA is altered for several bands; such a difference has been recently reported for cytoplasmic male sterile maize[14]. Since we have checked here that cp-DNAs of normal and male sterile lines are identical (Fig. 3, *a, b*) the male sterility mechanism seems to only involve the mitochondria.

All these mt-DNAs led to about 50 bands when split by *Eco*RI; this number is quite larger than that obtained with cp-DNAs, as illustrated on Fig. 1 (see ref. 6). The fluorescence intensity of several bands is greater than expected from normal stoichiometry and reflects the presence of multiple fragments. Even when these band multiplicities are not taken into account, the sum of the band molecular sizes estimated for virginia creeper, cucumber and wheat mt-DNAs were respectively 165×10^6, 120×10^6 and 140×10^6; these values are much larger than the native molecular weight (60 to 70×10^6) directly determined from the contour length by electron microscopy (pea[3]; virginia creeper, our unpublished results). The sum is only 90×10^6 for potato calluses mt-DNA, probably because of the presence of a multiple band of high molecular weight (first band on Fig. 1 gel *c*). This value, 90×10^6, is nevertheless larger than the native molecular weight estimated from the contour length (60×10^6, data not shown). All these banding patterns were rigorously reproducible in respect to both the relative position and the relative intensity of the bands; several DNA isolations, different batches of enzyme, different concentrations of enzyme, extended digestion time (12 h), phenol-treated digests and digests heated to 60 °C gave identical distributions. These electrophoregrams therefore represent non-reassociated limit digests.

The mt-DNA of *T. aestivum* var. Capitole has been exhaustively digested (7 h) by two other restriction endonucleases, *Bam*I and *Sal*I. The electrophoretic patterns are shown in Fig 4 and confirm that the sum of the fragment sizes remains quite larger than the native molecular weight, even when band multiplicities are not taken into account. The possibility that such discrepancies could result from a methylation cannot be ruled out, since methylation of a base in either strand of the endonuclease recognition site is sufficient to prevent the endonuclease from attacking the sequence[15]. Whereas it is agreed that cp-DNA does not contain 5-methylcytosine[16], no information is available about the presence of methylated bases into the mt-DNA of higher plants. This methylation should not occur randomly since the electrophoretic pattern remains unaltered (in number and size of fragments and in relative intensity of band fluorescence) for a given plant species, whatever the organ, the age of the plant or the growth conditions (data not shown).

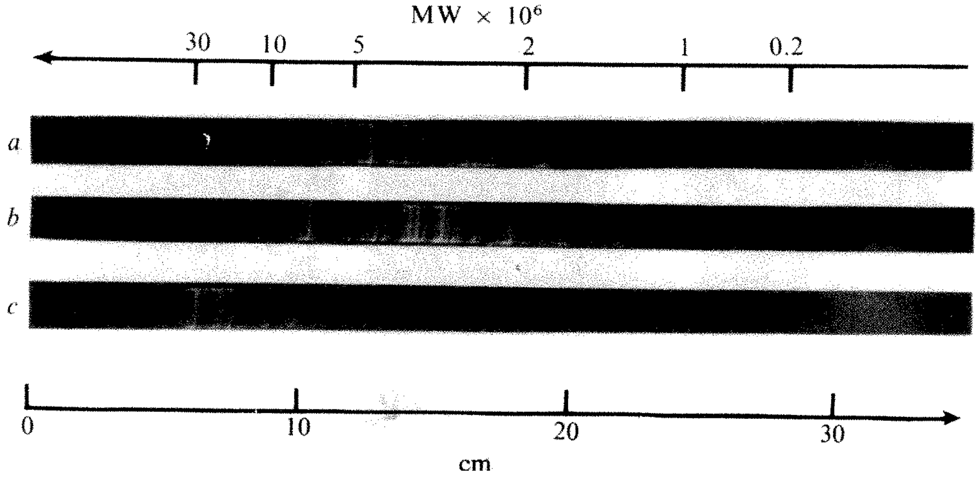

Fig. 4 Agarose gel electrophoresis of *Eco*RI (*a*), *Bam*I (*b*), and *Sal*I (*c*) digests of mt-DNA isolated from *T. aestivum* var. Capitole. Experimental procedure as for Fig. 1.

If methylation is to be ruled out, the main conclusion arising from above molecular weight discrepancies should be that the population of mt-DNA molecules is heterogeneous and that an higher plant contains different mt-DNA molecules. The plant mitochondrial genome would be constituted by several circular mt-DNA molecules with identical buoyant density but with some differences in sequence arrangement. The mitochondrial genome complement would be represented either by one mitochondria containing different circular mt-DNA molecules or by several classes of mitochondria[17], each containing one type of DNA molecule.

Whereas inter- and intraspecies variations have been detected for mammalian mt-DNAs, the mt-DNA of each studied mammal seems to be constituted by a single molecular clone, as evidenced by the good correspondence between the contour length and the molecular weight estimated from *Hae*III restriction patterns[18]. Higher plant mitochondria thus differ from mammalian mitochondria in this respect. Heterogeneity of this type has been reported for the kinetoplast DNA isolated from *Crithidia luciliae* and split by *Hap*II restriction nuclease[19].

The determination of mt-DNA restriction patterns, together with study of the chloroplastic DNA (ref. 6), should be very useful in analysis of phylogenies and in determining the nature of parasexual hybrids.

We thank Drs Y. Cauderon and P. Auriau (INRA, Versailles) for seeds of *T. aestivum* var. Gaines, and Dr Hoffnung (Institut Pasteur, Paris) for *Sal*I.

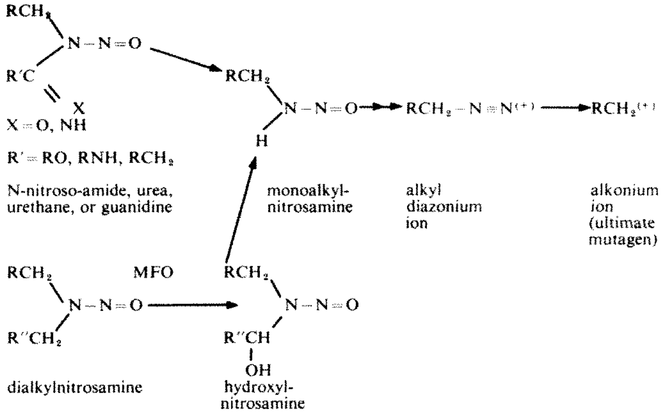
Inhibition by L-ascorbate of bacterial mutagenesis induced by two *N*-nitroso compounds

MANY chemicals are activated to carcinogens and mutagens by oxidative metabolism to alkylating agents[1]. Ascorbic acid has been reported to protect against tumour induction in mice by 3-hydroxyanthranilic acid, which induced bladder tumours[2] and 7,12-dimethylbenzanthracene plus croton oil which induced skin tumours[3]. Ascorbic acid can also prevent the formation of carcinogenic *N*-nitroso compounds from nitrite and amines, *in vivo*[4] and *in vitro*[5]. I report here that mutagenesis by two preformed *N*-nitroso compounds is effectively inhibited by ascorbic acid.

Many *N*-nitroso compounds are potent carcinogens and mutagens[6–8]. The mechanism of action of these compounds is believed to involve decomposition to short-lived highly reactive electrophiles which react with nucleophilic sites on DNA bases leading to altered bases[6–8]. Some of these alterations may not be fully repairable in certain tissues, and cause base pair substitution mutations, and perhaps lead to tumour formation[9,10]. There is evidence that the reactive electrophile and ultimate mutagen is an alkonium ion, which is formed by rapid intramolecular rearrangements subsequent to spontaneous scission of the derivatised α carbon of *N*-nitroso-amides, ureas, urethanes or guanidines[6–8]. *N*-nitrosamines also decompose to yield alkonium ions, but as their *N*-α-carbon bonds are not labile, nitrosamines must be metabolically activated by an αhydroxylase activity present in the mixed function oxidase (MFO) system[6–8].

These reaction pathways are depicted below:



As both types of *N*-nitroso compounds are believed to generate altered bases by an electrophilic attack on nucleophilic sites in DNA, it seems possible that an exogenous nucleophile could compete with DNA bases for the ultimate mutagen and thus serve as a possible preventative agent against mutagenesis and carcinogenesis. As tissue and biological fluids contain nucleophilic compounds which could also react with alkonium ions, this nucleophile would have to be more reactive than these endogenous nucleophiles if it were to be effetive. Alternatively, it could be of comparable nucleophilicity but be present in higher concentrations than endogenous nucleophiles in the proximity of DNA. It should also be non-toxic at the levels used. One such compound might be L-ascorbic acid. Although usually known for its anti-oxidant properties, L-ascorbate which is the predominant form at physiological *p*H, possesses substantial nucleophilic character[11]. In fact, it has been suggested by Edgar that ascorbate might protect against electrophilic attack on cellular DNA by intercepting alkylating agents[11]. In addition, it can be ingested in moderate quantities without apparent toxicity[12,13]. In this study the effects of ascorbate ion on microbial mutagenesis by *N*-methyl-*N*-nitrosoguanidine (MNNG) and dimethylnitrosamine (DMN), were examined.

Mutagenesis was assayed by a bacterial auxotroph reversion test using the histidine requiring *Salmonella typhimurium* tester strain TA 1530 described by Ames *et al.*[14]. The microorganisms were incubated with MNNG or DMN in 0.1 M phosphate buffer, *p*H 7.4, in the presence or absence of ascorbic acid. When DMN was used, a rat liver extract, containing the MFO system was incorporated into the incubation mix[15]. Aliquots were taken at several incubation times and reversion of microorganisms to histidine independence was assayed as described in Fig. 1.

In Fig. 1 the inhibitory effects on MNNG mediated mutagenesis by various concentrations of ascorbic acid are shown. Higher concentrations of ascorbate caused greater inhibition of mutagenesis. Mutagenesis by DMN, (Fig. 1*c*, *d*), is also inhibited by ascorbate. Higher concentrations of ascorbate are necessary to inhibit mutagenesis by DMN than by MNNG. The concentration of ascorbate necessary to produce a particular percentage inhibition of DMN-induced mutagenesis is a function of the concentration of liver extract in the incubation mixture. For example, when DMN was activated by

1.5 mg ml^{-1} liver extract, 90% inhibition was afforded by 1.5 mg ml^{-1} ascorbate. When twice the concentration of liver extract was used and other conditions held constant about twice the concentration of ascorbate was required for the same percentage inhibition. As both DMN and MNNG are believed to yield the same ultimate mutagen[6], it seems that the components of the liver extract rendered ascorbate a less effective inhibitor, since the MNNG mutagenesis system contained no added activation system. Since proteins contain a number of side chains with nucleophilic moieties it is possible that some of these may compete with ascorbate by reacting with the ultimate mutagen, thus decreasing the life-time of the mutagen. This effect seems to be important since added bovine serum albumin, 2 mg ml^{-1} in the absence of ascorbate, inhibited mutagenesis by MNNG by over 90%.

Alternatively the liver extracts might bind or deactivate ascorbate and thus lower its effective concentration. Some indirect evidence of this latter effect may be seen in the fact that in the absence of liver extracts ascorbic acid is toxic to the bacteria at concentrations above 0.3 mg ml^{-1}, but in the presence of liver extracts no toxicity is observed at concentrations as high as 3.0 mg ml^{-1}. Ascorbate toxicity has been reported with other strains of bacteria[16]. No significant toxicity was observed in the conditions used in this study. In view of these complications and the possibility of ascorbate interference in the activation of DMN to a mutagen, further studies were carried out with simpler MNNG system.

If there is in fact competition between ascorbate and microorganisms for the ultimate mutagen, then a further demonstration of this competition would be a decreased efficiency of inhibition by ascorbate at higher concentrations of microorganisms. As shown in Table 1, the percentage inhibition by ascorbate drops as the concentration of bacteria in the incubation mix increases. This effect and the increasing inhibition at higher ascorbate concentrations described above suggest that ascorbate exerts its inhibitory effect by trapping the ultimate mutagen before it interacts with cellular DNA.

Other biological nucleophiles also inhibited mutagenesis by MNNG (see Table 2). But none of those tested was as effective as ascorbate. The compounds tested were chosen because they contain most of the functional groups that are found in significant concentrations in biological fluids[17]. The actual concentrations of these compounds relative to ascorbate will vary in different tissues and with ascorbate intake. In urine for instance, ascorbate concentrations may be considerably higher than those used in this study[18], whereas the concentrations of the compounds in Table 2 are usually significantly lower[17].

The concentration of ascorbate necessary to effectively inhibit mutagenesis by MNNG can readily be exceeded in the urine[18], and may be reached in certain other tissues[18]. As this study indicates, a number of compounds normally found in urine are capable of inhibiting mutagenesis by MNNG; however, ascorbate is the most effective. It cannot be excluded, however, that ascorbate might be able to deactivate the parent *N*-nitroso compounds by some other mechanism such as reduction, which is not available to most of the compounds listed in Table 2. Several *N*-nitroso compounds are known bladder carcinogens in animals[8]. If the mechanisms of carcinogenesis and mutagenesis are similar[19], and if *N*-nitroso compounds are bladder carcinogens in humans, then some protective effect against these compounds might be afforded by saturating doses of vitamin C. In previous studies where ascorbate inhibited carcinogenesis its protective role was attributed to its role in preventing oxidative activation of carcinogens[2,3], presumably to electrophiles. It is possible that ascorbate may also exert a protective effect by intercepting electrophilic

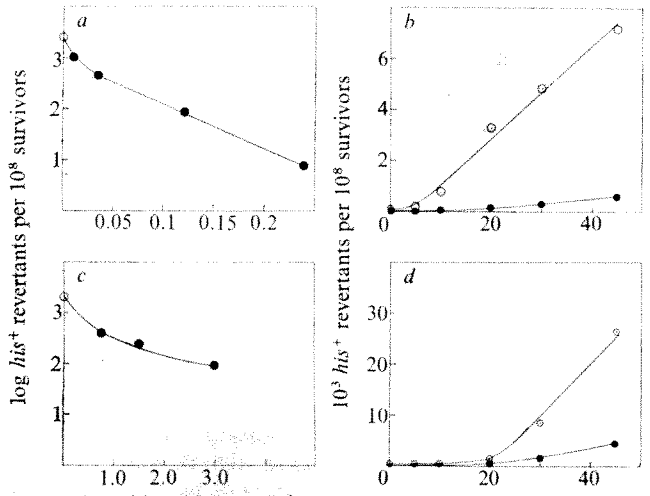


Fig. 1 Effect of ascorbate on mutagenesis of *Salmonella typhimurium* TA 1530 by MNNG and DMN. *a*, *c*, Effect of concentration of ascorbate on mutagenesis by MNNG and DMN respectively; *b*, *d*, effect of incubation time on mutagenesis by MNNG and DMN respectively. Reaction mixtures (0.5 ml) contained: bacteria, 2 × 10^8 c.f.u. centrifuged from a stationary phase culture; MNNG, 8.0 μM (*a*), 13 μM (*b*) or DMN 200 mM + liver extract from Aroclor pretreated rats[15], containing 1.5 mg ml^{-1} protein (*c*) or 3.0 mg ml^{-1} (*d*); 0.1 M phosphate buffer (*p*H 7.4); ascorbic acid, 0.12 mg ml^{-1} (*b*), 3.0 mg ml^{-1} (*d*) or varying concentrations (*a*) and (*c*). ○, no ascorbate; ●, ascorbate. Test tubes containing the incubation mix were shaken aerobically at 37 °C, for 15 min (*a*), 40 min (*c*) or varying times, (*b*) and (*d*). Bacteria were assayed for histidine independent (*his*$^+$) revertants and cell viability. Cell viability was not significantly decreased during the incubation. The spontaneous revertant frequency was < 10 per 10^8 c.f.u. and was not subtracted from the total revertants. Ascorbate may have been slightly mutagenic, as in the absence of added mutagen it caused a doubling in the revertant frequency. Revertant frequencies obtained from duplicate assays were within 15% of each other. *S. typhimurium* TA 1530 was kindly provided by B. Ames.

Table 1 Effect of concentration of bacteria on inhibition of MNNG mediated mutagenesis by ascorbate

Bacteria (× 10^8 c.f.u. per m)	Revertants ml^{-1} No ascorbate (R_0)	Revertants ml^{-1} Ascorbate (R_a)	R_a/R_0
2.6	3,380	300	0.088
4.6	4,840	1,260	0.26
6.5	11,010	3,590	0.33
13.0	14,020	6,250	0.45

Mutagenesis was assayed as described in Fig. 1. The incubation time was 15 min, the concentration of MNNG was 8.0 μM and that of ascorbic acid 0.06 mg ml^{-1}. c.f.u., Colony forming units.

Table 2 Effects of various biological compounds on mutagenesis by MNNG

Addition (mM)	$\frac{10^3 \text{ Revertants}}{10^8 \text{ c.f.u.}}$
—	3.0
Ascorbic acid, 6.8	0.04
Creatine·H_2O, 8.1	0.69
Cysteine·HCl, 7.6*	3.3
Methionine, 8.1	2.5
Serine, 11.4	0.43
Tyrosine, 6.6	0.62
Trypotphan, 5.9	0.54

Mutagenesis assay was as described in Fig. 1. The incubation time was 8 min and the concentration of MNNG was 8.0 μM. All additions were present at a final concentration of 0.12 mg ml^{-1}. Similar percentage inhibition was seen at longer incubation times.

*Cysteine became inhibitory at longer incubation times. At 2 h incubation when mutagenesis had nearly ceased it had inhibited mutagenesis by 50%. It was the only compound in this table to show this effect.

metabolites, or their precursors, independent of their mode of production.

I thank Miriam Miranda for technical assistance. This work was supported by the USPHS.

Note added in proof: Recent experiments have shown that addition of ascorbate to solutions of MNNG causes a rapid decrease in the absorbance of MNNG at 400 nm, whereas addition of the same concentrations of the other compounds in Table 2 had little effect. Some of the MNNG may thus be directly deactivated by ascorbate.

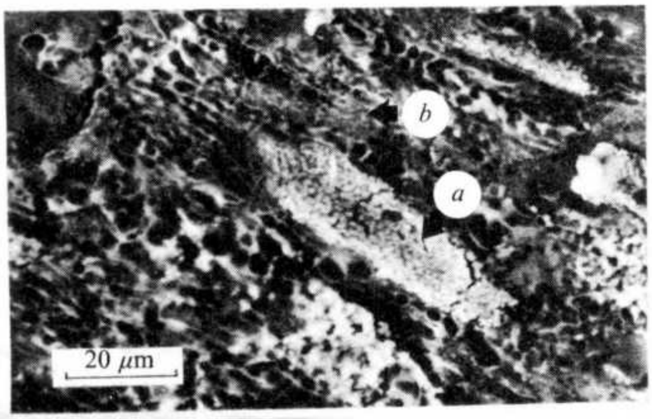
Intracellular cationic counterion composition of an acid mucopolysaccharide

EVEN though much is known about biopolymer synthesis and secretion, little or nothing is known about the exact identity of counterions bound to charged biopolymers inside cells. This may be very important since bound ions can influence polymer size and shape and so may hold answers to questions about polymer packaging in cells. In this paper we demonstrate how X-ray microprobe analysis of frozen mucus cells, from a marine snail, has enabled us to show that a sulphated mucopolysaccharide only binds potassium inside the cell but releases this to bind magnesium and calcium after secretion. This is of particular interest because, of all the common physiological cations, only potassium precipitates this mucopolysaccharide *in vitro*. The implication is that potassium could cause the polymer to adopt a more compact form within the cell.

Fig. 1 Scanning electron micrograph of a freeze-fractured face in the hypobranchial gland epithelium of the gastropod *Buccinum undatum*. Arrow A points to an acid mucopolysaccharide cell filled with vesicles while arrow B indicates an area of ciliated and interstitial cells. Both areas A and B were probed for elemental analysis by X-ray emission. The results are shown in Fig. 2 and Table 1. Probe spot diameters of about 2 µm were used.



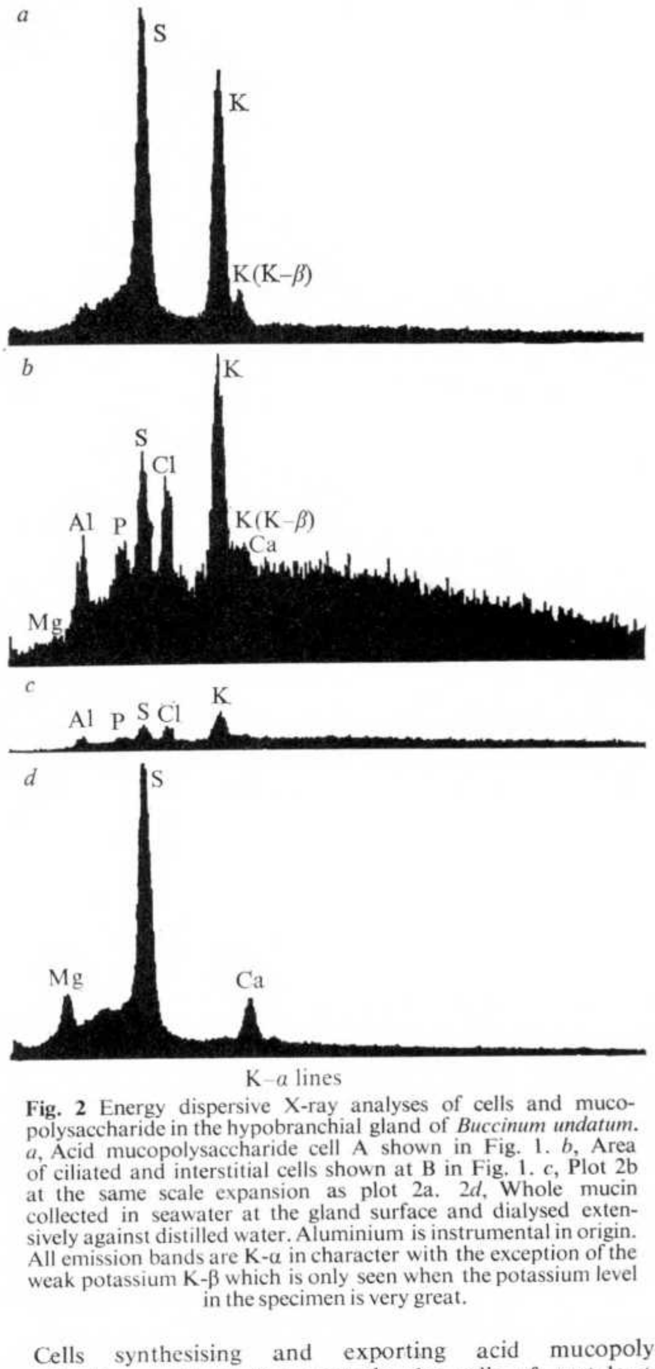


Fig. 2 Energy dispersive X-ray analyses of cells and mucopolysaccharide in the hypobranchial gland of *Buccinum undatum*. *a*, Acid mucopolysaccharide cell A shown in Fig. 1. *b*, Area of ciliated and interstitial cells shown at B in Fig. 1. *c*, Plot 2b at the same scale expansion as plot 2a. 2*d*, Whole mucin collected in seawater at the gland surface and dialysed extensively against distilled water. Aluminium is instrumental in origin. All emission bands are K-α in character with the exception of the weak potassium K-β which is only seen when the potassium level in the specimen is very great.

Cells synthesising and exporting acid mucopolysaccharides, such as for example the cells of vertebrate cartilage or the epithelial gland cells of many marine invertebrates, must experience a problem of cationic balance. From the moment that the polymer first receives its charged groups, whether these be carboxyl or sulphate, the intense electrostatic field generated by the polyanion will attract an atmosphere in which cations will predominate; moreover, as with polyelectrolytes generally, a substantial proportion of these cations will be bound specifically as ion pairs. There is evidence indicating that there may be orders of preference of binding different cations by differing anionic groups[1,2] and suggesting that different polymers may show different cation specificities[2]. The type of counterion bound may in some cases radically affect the polyanion conformation[3].

Whether polyanion synthesis is accompanied by a continuous export from the cell or by storage in vacuoles for bulk secretion, the cytoplasm of the cells would experience an unusual demand on the free cation pool, which has to be restored by inward transport of cations. Moreover, should the polyanion show cation specificity, unusual imbalance in the cation composition of the cell may develop with obvious implications. These are possibilities which can only be speculated on in the absence of information about the counterion distribution surrounding polyanions.

Although determination of the ion-binding properties of an acid mucopolysaccharide outside the cell is relatively easy, it has hitherto been impossible to determine the intracellular counterion distribution accompanying the polyanion. We have now carried out such an analytical electron microscopic study using a secretory epithelium from the marine gastropod *Buccinum undatum*. We chose this tissue rather than vertebrate connective tissue cells for an initial investigation because the polysaccharide produced is fairly simple, containing only ester sulphate and no carboxyl groups[4,5], the tissue has been well described ultrastructurally[6], the secretion vesicles inside the cell are readily seen in the electron microscope[6] and finally, because the presence of ester sulphate and little or no amino acid sulphur in the mucopolysaccharide allows for straight comparison between sulphur and cation X-ray signals in the analytical microscope. We used the hypobranchial gland, which secretes a mucin into the mantle cavity of the mollusc and is a folded epithelium with a large population of secretory and ciliated cells. Mucin forms by the mixing of two secretion products at the gland surface. One product, the polyanion, is essentially cellulose with one ester sulphate residue per glucose unit[4,5], and the other, formed in a different cell type[6], is a neutral glycoprotein.

Since any form of fixation, dehydration and embedding would have radical effects on cation content in the tissue we adopted the strategy of quench–freezing freshly excised tissue in 'slushy' liquid nitrogen, placing the frozen specimen in the scanning electron microscope and cleaving the tissue on the freezing stage *in vacuo* with a scalpel blade. The cells are exposed in fractured section and vacuum sublimation sufficiently etches the cleft surface to make tissue topography readily recognisable when compared with conventional micrographs[6]. Figure 1 shows such a cleft surface, acid mucopolysaccharide cells are clearly distinguishable from other cells. Electron beam probing and energy dispersive X-ray analysis applied to the secretion vacuoles of these cells gave the results typified in Fig. 2*a*. Interestingly high sulphur and potassium peaks dominated the spectrum and no other cation peaks were seen in these plots. Probing non-mucopolysaccharide cells in the tissue gave results typified by Fig. 2*b* and *c*. These are shown at the same and greater scale expansion as the acid mucopolysaccharide cells, to emphasise the high levels of potassium and sulphur present in the secretory vaccuoles relative to the ionic content of the general cytoplasm of other cells.

Since we had shown that the polyanion probably exists in the cell solely as the potassium salt, we tried to determine whether the counterion is altered when the polyanion is released into the seawater medium. It is at this time also that polyanion and glycoprotein interact to form a rheotropic mucin. Figure 2*d* shows the X-ray analysis of a mucin sample collected under seawater as it left the gland. The mucin had been transferred immediately to distilled water, dialysed extensively and freeze-dried. Potassium has gone from the trace completely and has been replaced by magnesium and calcium. Sodium too, is absent. Dialysis of the mucin against seawater before distilled water does not alter this pattern.

A difficulty about this technique is its semi-quantitative nature. X-ray counting efficiency falls off rapidly for atomic numbers below 15 and so on an atom-to-atom basis sulphur and sodium peaks should be in approximately 10 : 1 ratio, whereas equivalent heights of sulphur and potassium peaks are more nearly indicative of equivalent atomic ratios. Nevertheless, the height of the magnesium peak indicates that sodium would be detected if present.

In Table 1 we show the integrated values of the elemental peaks seen in Fig. 2*a*–*c* as well as values for scans of the purified acid mucopolysaccharide as its potassium and sodium salts and in the ionic form generated by dialysis of the potassium salt against seawater. Attempts to replace potassium by sodium using high salt concentrations or sodium-form ion-exchange resins fail to remove all potassium. The reverse is not true. Like whole mucin, pure polyanion exposed to seawater loses all detectable monovalent cation, gaining mainly magnesium and somewhat less calcium.

Thus it seems that the polyanion is synthesised and stored as the potassium salt but changes in the sea to the magnesium–calcium form, in spite of the availability of sodium, magnesium and calcium inside the cell. Intracellular ionic compositions are difficult to obtain, depending on knowledge of extracellular space volumes. As an example, however, we quote analyses[7] of squid muscle cells with values of 30.8, 189, 1.88 and 19.0 mg ions per kg water for Na, K, Ca, Mg respectively, with seawater containing 492, 10.5, 10.8 and 56.1 mg ions per kg respectively of the same ions. The high concentration of sodium in seawater seems not to affect the ability of the polyanion to bind divalent ions which also compete very successfully with potassium. Since magnesium and calcium, albeit at low concentrations, are probably present in the cell why do they not also compete there with potassium for binding sites? Of interest here is the fact that concentrations of potassium ions in excess of 0.2 M *in vitro* precipitate the polysaccharide sulphate and this we use as a purification step[4]. This property is shared by some other polysaccharide sulphates, for example, K-carregeenan[8]. Excess concentrations of sodium, magnesium or calcium salts do not have this effect.

Packaging is important for the cell since most acid mucopolysaccharides hydrate readily and attempt to occupy large

Table 1 Integrated elemental X-ray counts for tissue and isolated acid mucopolysaccharide preparations from the hypobranchial gland of *Buccinum undatum*

	Na	Mg	P	S	Cl	K	Ca	Scale expansion
Acid mucopolysaccharide cell (Fig. 1)	0	0	0	26,564	0	20,559	0	4
Non-secretory cell (Fig. 1)	not measurable	120	300	1,259	995	2,122	210	7
Whole mucin after secretion into seawater	0	5,630	0	49,538	0	0	8,000	3
Acid mucopolysaccharide dialysed against seawater	0	4,669	0	63,724	0	0	7,108	3
Acid mucopolysaccharide, potassium form	0	0	0	49,524	0	38,784	0	3
Acid mucopolysaccharide, sodium form	13,860	0	0	130,728	0	6,602	0	2

X-ray energy dispersive spectra were obtained using a Jeol JSM 50A scanning electron microscope in conjunction with a Kevex analyser. Specimens were mounted on carbon stubs and maintained in the microscope at a stage temperature of −104 °C. Exciting voltages, count times and take off angles were held constant at values of 20 KV, 100 s and 30° respectively for all specimens. Vertical scale expansions were varied to accommodate X-ray yields (which are sensitive to specimen thickness and density) at major elemental peak heights. In the case of non-secretory cells X-ray continuum made sodium counting of the low levels present non-productive.

aqueous domains. These are manifested as extensive bulk-swelling properties and abnormal viscosity–concentration relationships. This is what happens here because the polymer leaves the cell and enters the aqueous medium when the released mucopolysaccharide vesicles can actually be seen in micrographs swelling and bursting and when viscosity measurements on newly released mucin show large increases in reduced viscosity accompanying dilution[5,6]. But why does the polymer remain relatively unswollen within the cell? The environment is still aqueous and a rapid and catastrophic domain expansion might be expected, but this patently does not occur. The finding that the polyanion exists intracellularly as the potassium salt, coupled with the observation that this salt is somehow different in conformation or charge distribution from other cation forms, may explain the ability of the cell to keep the polyanion packaged. This (may be achieved by maintaining specific inward membrane-mediated pumping of potassium while specific exclusion of other cations at the polyanion vesicle membranes may explain the failure of the magnesium–calcium salt to form.

We thank Professor Charles Phelps and Drs Ian Nieduszynski and John Sheenhan for helpful discussions.

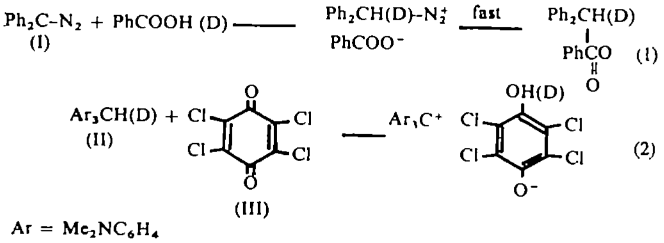
Pressure effects on proton tunnelling

We report here the first measurement of the effect of pressure on primary kinetic isotope effects of reactions in the liquid phase. We have determined rates of two reactions in solution by a sampling technique at pressures up to 2 kbar using both normal and deuterium-labelled reagents as indicated. Reaction (1) is between benzoic acid and diphenyldiazomethane (I) which has been shown to proceed by a rate-determining proton transfer[1,2]. Reaction (2) is between leuco crystal violet (II) and chloranil (III) in which the slow step is a hydride transfer[3].



In the butyl ether solvent used, reaction (1) exhibits an isotope effect which is in the normal region ($k_H/k_D = 4.5$), that is, accountable in terms of differences in zero-point energy and vibrational frequencies of reagents and transition state[4]. The abnormally large isotope effect ($k_H/k_D = 11.2$) in reaction (2) has been assumed to be due to a tunnelling contribution.

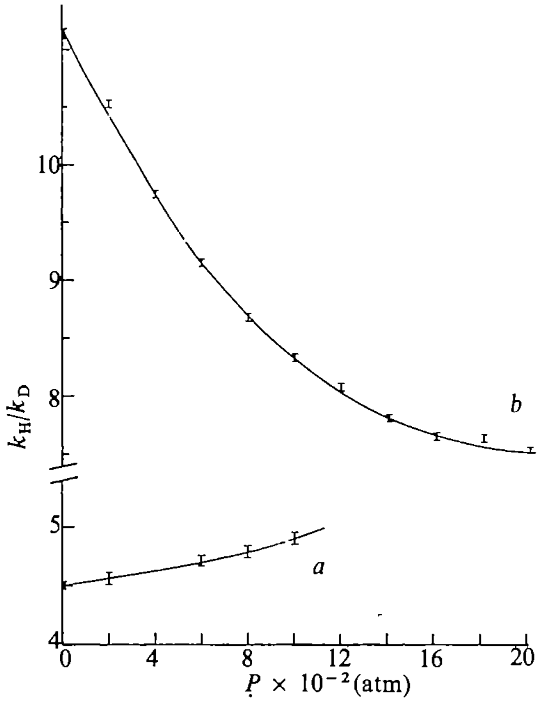


Fig. 1 Effect of pressure on the kinetic isotope effect of hydrogen transfer reactions. *a*, Reaction of diphenyldiazomethane in dibutyl ether at 26.5 °C; *b*, reaction of leuco crystal violet in acetonitrile at 29.5 °C.

We find that the behaviour of the two isotope effects under pressure is quite different. That of reaction (1) remains almost invariant while that of (2) smoothly decreases until at 2 kbar it levels off at a value near the maximum 'normal' ratio of about 7.5 (Fig. 1). It follows that the volumes of activation, $\Delta V^\ddagger$, calculated (using the regression equation $\ln k = A - \Delta V^\ddagger/RT + CP^2$)[5] for reactions (1) (H) and (1) (D) are the same (-12.8 cm^3 mol^{-1}) while those of reactions (2) (H) and (2) (D) are very divergent, being -25.5 and -35.8 cm^3 mol^{-1} respectively.

It is assumed with good justification that isotopic substitution does not alter the reaction pathway or position of the transition state along the reaction coordinate[6]; therefore it seems likely that the value of $\Delta V^\ddagger$ for reaction (2) (H) is anomalous because of a tunnelling component. In this reaction external pressure serves to lower the potential barrier to the activation process. Consequently a higher proportion of reagents will be capable of surmounting the barrier normally and the relative importance of tunnelling will diminish with increasing pressure analogous to the effect of an increase in temperature[7]. This analysis suggests that the tunnelling contribution of a reaction with a positive volume of activation (that is, which has a rate decreasing with pressure) and consequently the isotope effect, should increase with pressure. In general, where tunnelling is important, $\Delta V^\ddagger(\text{H}) < \Delta V^\ddagger(\text{D})$.

Although more data are needed to give confidence to this interpretation the result suggests that pressure dependence of the isotope effect may serve as a further criterion of the occurrence of tunnelling in hydrogen-transfer reactions.

Generalisation of self-thinning of plant populations

WESTOBY'S attempt[1] to generalise self-thinning of plant populations by relating leaf area per plant (*L*) to surviving plant density (*p*) is spurious. The result, therefore, is not of 'more general application than the original statement of the rule'[2].

The measured value of leaf area index (LAI) in many plant stands may vary from <1 to 20, but rarely exceeds 10 (refs 3, 4, 5). Westoby's Fig. 3 shows not merely an error in graphical labelling (the ordinate values are 10 times too large), but reveals a more fundamental misconception about the dynamics of thinning. The relationships between leaf area (*L*) and dry weight (*W*) shown in Fig. 2 are not applicable to the experimental circumstances depicted in Fig. 1 on at least two grounds. Firstly, Blackman & Wilson[6] derived their leaf area ratios (LAR= *L*/*W*) from spaced plants (~20 plants m^{-2}). LAR varies significantly with density[3,7,8] and with light intensity[6] (as Fig. 2 shows) and may vary with age[9]. Secondly, the range of *W* in Fig. 2 seldom exceeds 1.0 g, whereas its range in Fig. 1 is generally an order of magnitude greater: the extrapolation of equations derived from Fig. 2 over this range is unjustified. The neglect of density effects on LAR, coupled with graphical extrapolation cause the error in Fig. 3.

The behaviour of LAI in plant stands (both of herbs and trees) is simply stated: it rises rapidly, as a function of density and light intensity *inter alia*, to a plateau value, which is commonly <10. Thinning may occur while LAI is increasing and/or for a prolonged period while LAI remains constant, or even declines. The most general statement of the dynamics is $L = K^{-1}$ [9], where *K* varies significantly with light intensity. This is shown very clearly for *Helianthus annuus* in the original source from which Fig 1 was derived: 'the convergent leaf area index at 100%, 60% and 23% daylight was respectively 8, 6.5 and 1.5' (ref. 3), an empirical result which belies Fig. 3, where stands with least light have highest LAI for a given chronological age!

It should also be noted that the author's use of *K* in both equations relating *W* and *L* to *p* is misleading, as it implies similar constants: they are quite different.

WESTOBY REPLIES—I thank Dr White for his helpful remarks. Firstly, he is quite correct that the scaling of the *y* axis in my Fig. 3 was ×10 too high; I apologise for confusing readers. Figure 3 was not intended as a simulacrum of a real experiment, but as a demonstration that the response of LAR to shading is the right kind to return the slope of a low-light thinning line to −3/2. That remains my basic point. Certainly LAR responds to planting density, among other factors. But does high planting density obliterate the response of LAR to shading?

I should like to suggest that perhaps the underlying determinant of relative mortality rate is how fast the light climate is deteriorating for the smallest plants in the population. Which descriptor of the population would correlate best with this process would depend on circumstances. During early growth biomass would be adequate unless LAR was varied by light treatments, in which case leaf area would be better As the death rate of leaves rises LAI asymptotes, but the location of the canopy continues to rise, which has the effect of putting the smallest plants lower in the light profile. Here cumulative production of leaf area or biomass (as measured by Hiroi and Monsi) would be the most relevant descriptor. Where stem production is cumulative and comes to dominate the biomass (for example, in tree stands), stem weight or volume will be the best available indicator of cumulative leaf area production.

Atlantic palaeotemperatures during the Cainozoic

IT is comparatively easy to make generalisations in palaeo-oceanography, and Cifelli[1] has made several postulates regarding the Cainozoic palaeotemperatures of the North Atlantic; but the test of speculation in palaeo-oceanography is detailed biostratigraphy. For example, Cifelli[1] postulated that during the Miocene, the North Atlantic Gyre "extended perhaps 10° further north than they do now". The limited evidence, by Berggren[2], DSDP Leg 12, Sites 116 and 117 hardly support this: Berggren's[2] zonation of the Miocene planktonic foraminifera is reminiscent of that established in the cooler higher latitudes of New Zealand[3,4] than of the tropical belt zonations by Bolli[5] and Blow[6]. Work recently completed[7] on a cored Lower Miocene Burdigalian borehole sequence 110 km south-west of the Isles of Scilly has yielded an excellent planktonic foraminiferal fauna which lacks the following warm-water taxa recorded in Trinidad[2]: *Globigerina venezuelana* Hedberg, *Catapsydrax unicavus* Bolli, *C. dissimilis* (Cushman and Bermudez), *C. stainforthi* Bolli, *Globorotaloides suteri* Bolli, and *Globigerinatella insueta* Cushman and Stainforth. Conversely, the fauna contains cooler water modern species such as *Globigerina bulloides* d'Orbigny and *Turborotalita quinqueloba* (Natland) as well as cooler water extinct fossils such as *Globigerina woodi* Jenkins and *Globorotalia zealandica* (Hornibrook).

Thus from the limited, but accumulating evidence available, the planktonic foraminfera in Miocene of the North Atlantic indicate that near-surface palaeotemperatures of the ocean were not as warm as postulated by Cifelli[1].

There is well documented evidence[8] which clearly indicates that a number of species such as *Globigerinatella insueta* Cushman and Stainforth, *Globorotalia fohsi fohsi* Cushman and Ellisor, *G. fohsi lobata* Bermudez and *G. fohsi robusta* Bolli were restricted to the tropical belt in the Miocene, with cooler water in the higher latitudes such as the North Atlantic.

[8] Jenkins, D. G. *Micropaleontology* **11**, 265–277 (1965).

CIFELLI REPLIES—Clearly, the proposal that warm gyral water was greatly expanded in the North Atlantic during the Miocene needs further testing against the evidence of the fossil record. But in dismissing this generalisation as idle speculation, Jenkins seems to have lost sight of my arguments and has shown nothing incompatible with 'detailed biostratigraphy'. DSDP Sites 116, 117 were interpreted oceanographically as gyral margin, not tropics and there is no reason to expect an identity in composition of faunal zones. Plankton assemblages of North Atlantic gyral margins are characterised by mixed associations of cool high latitude and sub tropical species plus lesser numbers of tropical expatriates displaced to the north by the clockwise movement of the circulation[1]. Mixed associations of this kind are well represented in DSDP Sites 116, 117, as discussed in my paper. If zonation of DSDP Sites 116, 117 reminds Jenkins of New Zealand zonation, then the oceanographic significance of the latter deserves reconsideration. That is, if faunal associations are mixed, as in DSDP Sites 116, 117 margins of warm gyral water may also be represented in the New Zealand Miocene.

Jenkins points out that a bore hole of Lower Miocene age near the Isles of Scilly lacks some 'warm water' species found in Trinidad. The species, however, that he lists are all extinct ones and the nature of the habitat they occupied is unknown. Actually, those species are either the same as, or closely related to, Oligocene species which are more analogous morphotypically to modern cold water than warm water forms[2]. They are a bad choice for warm water indicators.

Jenkins' claim that certain species, notably the *Globorotalia* fohsi group is restricted to the tropical belt is nullified by Bartlett[3] who recorded that species group and other tropical or subtropical forms from Nova Scotia.

U-shaped gene frequency distributions

GILPIN *et al.*[1] have recently questioned the usefulness of the frequency distribution of allele frequencies as a means of distinguishing between the neoclassical (neutralist) and balance (selectionist) interpretations of genic variation in natural populations. The conventional view has been that random genetic drift will generate a U-shaped distribution of allele frequencies at equilibrium, while all allele frequencies will be equally probable if they represent stable equilibria maintained by the superiority of heterozygotes. Gilpin *et al.* argue that the assumption of equiprobability is gratuitous, and that the frequency distribution of allele frequencies amongst overdominant loci will be determined by the joint probability distribution of the selection coefficients acting on the homozygotes. In particular, U-shaped frequency distributions are to be expected if the probability of obtaining a given selection coefficient falls off steeply with the magnitude of the coefficient. Such a distribution of selection coefficients seems plausible, and is in any case similar to that which is claimed to be the case by the neutralist school.

The result obtained by Gilpin *et al.* applies to overdominant loci, treated deterministically. It may be worth pointing out that a U-shaped equilibrium distribution of allele frequencies will also be generated deterministically amongst loci at which the heterozygote is intermediate in fitness. Consider a locus with two alleles, *A1* and *A2*, whose frequencies are p and q respectively. If the selection coefficient and the degree of dominance are given, the rate of substitution will vary directly with the genic variance, pq. Since this is maximal at $p=q=\frac{1}{2}$, and is minimal when either allele is near fixation, substitution will proceed rapidly at intermediate allele frequencies, but very slowly when either allele is very common. If we imagine an ensemble of loci behaving in this way, it is easy to see that most loci will accumulate in the regions where the rate of movement of allele frequency is lowest, that is near $p=1$ and near $p=0$. In this way, the frequency distribution of allele frequencies at loci which are undergoing directional selection in an infinite population will be U-shaped at equilibrium.

GRAHAM BELL

Department of Biology,
McGill University,
Montreal, Quebec, Canada H3A 1B1

[1] Gilpin, E. A. *et al. Nature* **263**, 497–499 (1976).

ONDRICEK *et al.* REPLY—Bell correctly notes a possibility we had not considered, namely that the commonly observed U-shaped allele frequency distribution is to be expected assuming that polymorphic loci are in the process of becoming fixed for a better allele; this is simply because the fastest rate for change of transient polymorphisms is at intermediate gene frequencies.

Two predictions follow from his model. The first is that the rate of evolution of a population is proportional to its level of heterozygosity. There are insufficient data to test this, but the common finding of high heterozygosities in physically stable environments (the deep sea[2,3] and the tropics[4,5]) is not auspicious. Nor is the occurrence of moderate levels of variation in a 'living fossil', *Limulus polyphemus*[6], consistent with such a theory.

Second, the transient polymorphism model would predict that frequencies in the middle range, say 0.7 to 0.3, should not be conserved; that is, if related species or isolated populations of the same species share polymorphisms with allele frequencies in this range, it would argue for balancing selection. Tenacity for intermediate allele frequencies seems to be rather common. For example, the *Lacerta* data[7] show that *L. melisellensis* retains two alleles at intermediate frequencies for phosphoglucomutase-2 on all islands larger than 0.05 km², and *L. sicula* shows the same pattern for esterase-4. Among four species of the *willistoni* group of *Drosophila*, the analogous pattern is observable for aldolase, xanthine dehydrogenase, and adenylate kinase-2 (ref. 4). The examples could be multiplied.

In summary, we think it likely that only a small fraction of polymorphic loci are transient, and in the process of becoming fixed for an overall 'better' allele.

reviews

Mayr's evolutionary mission

A. J. Cain

Evolution and the Diversity of Life: Selected Essays. By Ernst Mayr. Pp. ix+721. (Belknap/Harvard University: Cambridge, Massachusetts, 1976.) £15.

THIS book is most likely to be reviewed by those for whom it is not intended (myself included). At first sight it is a strange collection of scientific papers (not essays like Julian Huxley's), whole or more usually excerpted, classed under the headings: evolution, speciation, history of biology, philosophy of biology, theory of systematics, the species, man (merely a blast—well aimed at the time—against the excessive taxonomic splitting of fossil hominids), biogeography and behaviour. Some, such as Mayr's paper on change of genetic environment and evolution (1954), propounding a theory of genetic revolution in peripheral populations, are major contributions to evolutionary theory at a professional level; others, now translated into English, are elementary expositions of neo-Darwinian theory for the benefit of continental audiences.

Useful, indeed sometimes excellent, studies of important but neglected or misunderstood biologists (Lamark, Louis Agassiz, Karl Jordan) are in the book, together with a ponderous (but correct) reply to Hennig's extraordinary ideas on evolutionary systematics, which could have been shortened, and tantalising snippets on topics as important as: accident or design (four pages); explanatory models in biology (five pages), and theory formation in developmental biology (six pages). The book is especially rich, as would be expected, in papers on speciation, the species and biogeography, although in the last only general discussions and conclusions are given, detailed documentation being left out. Throughout, papers have been adapted for this volume, but I am told that in every case where the author has changed his opinion this is duly noted between square brackets, so that the reader can see his intellectual progress. Mayr says himself in the general introduction that where he has included several essays on the same subject, this is done to "illuminate the maturation in my thinking". It would seem then that there is something in the book for everyone, although perhaps not much for some.

I think this is true. Mayr has a better acquaintance with European continental evolutionary biology than many westerners, and is probably the best judge of what is useful among his papers for the continental readers. Anyone in Britain or the United States might be inclined to dismiss his two papers for continental audiences as not worth reprinting, but the appearance of Grassé's book, *L'Evolution du Vivant,* (1973) makes one pause. If this is the best that the doyen of French zoology can do, then a vast amount of elementary instruction is needed on the continent before one can even start discussion. Although he has acquired some reasonably up-to-date references, Grassé is still well within the tradition set by Flourens's notorious attack on the *Origin of Species.* Some of the papers in Mayr's book are in journals not easy to come by, and more people than European continentals, in particular undergraduates and pre-doctoral students, will find the collection extremely useful. What is there in it for others?

Any evolutionist or historian of biology will be interested to see how Mayr's thought has changed since 1940, but he will have to work out the changes for himself, and must refer to other papers not included in it. I am very grateful to Ernest Mayr for outlining to me the principal changes (the notes that follow are, however, mine). In 1942, following the theory accepted then, he thought of polymorphism as neutral, but in 1945 (in a paper in *Lloydia* not, alas, included in the book) he had already come to see that selection must be acting. Formerly he regarded evolution as basically a change in gene frequencies but in the 1970s as a change in organisms, that in gene-frequencies being merely a consequence of selection on organisms. Formerly, he took the view that evolution would go fastest and speciation would be most frequent in big populations, but now he thinks that small peripheral populations, that have undergone a genetic revolution when they have been established, are the principal source of new evolutionary forms.

Coordinate with this is his strong emphasis on the genotype not as a 'bean-bag' of genes but heavily coadapted. In systematics, he points also to a sorting out of the ideas of the species as a taxon and as a category, previously confused in some of his earlier papers. In the highest levels of evolutionary theory, he is most impressed by the advent of population thinking, in which one is dealing with populations of interacting individuals, each of which is unique. It is clear from the book that he was profoundly impressed by a public encounter with Niels Bohr in which that great man seemed to misunderstand completely the greatest advance in biology. We have all met lesser men who enunciate such gems as "Molecular biology *is* biology, and all biology *is* molecular biology". Mayr has seen too much of the diversity of living things and the emergence of levels of organisation to be content with such a half-truth. He has always been well ahead in his appreciation of the complexities of natural selection, the enormous fluctuations in its rate, in short the biology of selection in the wild, although it took him some years (not documented here) to absorb the British work on the subject, and he apparently still puts faith in historic accident determining characters of great groups, and in the selective equivalence of isoalleles. This is not suprising as his own work has lain almost entirely in long-term evolution and the results rather than the action of selection.

This is a missionary book, against ignorance of the modern evolutionary synthesis, against the distortion of biology by molecular biologists, against the distortion of systematics by *a priori* considerations and against the neglect of major personalities in the development of evolutionism. Unfortunately, the style is not that of a missionary but a crusader, who believes that the only good heathen is a dead one. To be told that gradual evolution was accepted quite universally soon after 1859, that there is no such thing as mutation pressure (p 12) and yet that it has some direct results at the cellular level (p 111), is rather bludgeoning. Such remarks as "Thousands of experiments have proved that..." (no references), and "Discoveries in modern biology indicate that..." (no references) are more reminiscent of political propaganda. The missionary may have spoken more truly than he knew in saying (p 34) "Merely asserting [these claims] dogmatically will not convince those who, until now, have been disbelievers". It may even unsettle belief. What is the actual evidence not that genes interact but that genotypes are coadapted? □

A. J. Cain is Derby Professor of Zoology at the University of Liverpool, UK.

Plant transport processes

Transport in Plants. Vol. 3: Intercellular Interactions and Transport Processes. Edited by C. R. Stocking and U. Heber. Pp. xxii+517. (Springer: Berlin and New York, 1976.) DM145; $59.50.

THIS is the third volume covering transport process in plants in the new series of the *Encyclopaedia of Plant Physiology*. The first two volumes covered phloem transport and transport in cells, tissues and organs. This third multi-author volume is concerned with intracellular interactions and transport processes, a topic of considerable current interest which received little coverage in the first series published 1955–58. Indeed, as the editors point out, this is an area which is still poorly understood, particularly in relation to plants. This last point is illustrated by a glance at the references cited in many of the chapters, a high proportion being concerned with animal or microbiol systems. Thus, although this volume should become outdated fairly rapidly, it will serve as a useful summary of progress to date and as an indicator for future research.

The book is divided into four major sections concerned with membrane structure, intracellular interactions, transport in relation to energy conservation, and the theory of membrane transport. There is a little overlap with the second volume in the series in the first and last of these sections as regards membrane structure and the principles of irreversible thermodynamics. This is largely unavoidable and, in general, this volume complements the others very well.

The first section containing one chapter on plant membranes is disappointing. For example, the few pages on membrane isolation are really too superficial for an encyclopaedia; a number of the subsections are covered by reference to one or two reviews of work on animals. The treatment of plant plasma membranes could also be misleading. Lists of characteristics and markers are given, although these are based on only a handful of papers and are the subject of considerable current debate.

The second section of eight chapters covers intracellular interactions involving the nucleus, chloroplasts, the organelles concerned with photorespiration, mitochondria, vacuoles, and the endomembrane system. The chloroplast is particularly well reviewed in three chapters concerning re-cycling, export and storage in this organelle, metabolite carriers, and compartmentation and transport in C_4 photosynthesis.

It is clear that, although we know a great deal about the structure and separate biochemistry of various individual organelles, our knowledge of their transfer processes and interactions is still in its infancy. This is illustrated by the discussion of the importance of inorganic pyrophosphate in maintaining maximal photosynthetic rates in intact, isolated chloroplasts; it is thought to work by regulating the movement of orthophosphate into the chloroplast. Although this process probably is completely artificial, it indicates the role of the cytoplasm in regulating photosynthetic rates *in vivo*.

The importance of the treatment of chloroplasts after isolation, often given less attention than the isolation procedure itself, is stressed and deserves much wider consideration. The chapter on vacuoles further emphasises the difficulty of studying organelles in isolation from the cytoplasm, although the digestive lysosomal-like role of the vacuoles now appears to be well established.

The third section of three chapters is concerned with ion tranport and energy conservation and transfer in chloroplasts and mitochondria. Work on chloroplasts, in particular, provides strong support for the chemiosmotic interpretation in the great phosphorylation debate. The final section and chapter reviews the basic concepts used in the theoretical analysis of membrane transport processes.

The book is well illustrated and contains a thorough author and subject index. Although a number of the topics have been recently reviewed in other volumes, and in some cases by the same authors, they are here brought together in a single volume which, overall, lives up to the high standards set by the preceding numbers in this series.

Point defects

Point Defects in Crystals. By R. K. Watts. Pp. vi+132. (Wiley-Interscience; New York and London, 1977.) $27.90; £16.50.

THIS monograph deals with the magnetic resonance and optical properties of point defects. The first six chapters are theoretical. They cover electronic states of defects with tightly bound electrons (rare earths, transition metals, the F centre), with loosely bound electrons (donors, acceptors, excitons), vibrational properties (localised modes, vibronic transitions, the Jahn-Teller effect), defect chemistry (equilibria, thermodynamic potentials), theory of experimental methods (the spin Hamiltonian, optical properties), and electrons in covalent and ionic crystals. But this is not a textbook; supplementation by more pedagogic texts will be necessary. And the level is too advanced and too specialised for undergraduates, though suitable for postgraduates.

The next four chapters are reviews of point defects in the group IV, III–V, II–VI and alkali halide crystals. Materials dealt with include Si, Ge, diamond, GaP and GaAs. The II–VIs and alkali halides are dealt with by considering the defects and their manifestation in the different compounds, rather than by taking each compound individually. The coverage is thorough, although the author does not claim that it is exhaustive. The latest references are 1974 to 1976, depending on the material.

Reviews are, however, sooner or later overtaken by events, and this has already happened in at least one material Dr Watts has covered—diamond. This illustrates a problem inherent in reviewing fields of research other than one's own. (From the references it seems that Dr Watts's subject is the II–VI compounds.) Although the picture he presents of defects in diamond is largely correct, it is incomplete. And the identification of one important defect, though generally accepted before 1972, is widely disbelieved now. A diamond specialist would be aware of all this. One wonders if any of the other chapters have the same deficiency.

Nonetheless, the book is a useful introduction to the spectroscopic properties of these materials, provided it is supplemented by attention to the current literature and to more specialised reviews.

John Walker

John Walker is a Royal Society European Programme Research Fellow studying point defects and ion implantation in diamond with the Groupe de Physique des Solides de l'Ecole Normale Supérieure, Université Paris VII.

Volcanoes and eruptions

Volcanoes of the Earth. (Revised edition.) By Fred M. Bullard. Pp. 579. (University of Texas Press: Austin and London, 1976.) £20.

Volcanoes of the Earth is, as the dust jacket blurb states, a revised and enlarged edition of Bullard's *Volcanoes: In History, In Theory, In Eruption*, first published in 1962. It is a handsome volume, very satisfying to leaf through and to have on one's shelves. In contrast to the numerous cheaply produced textbooks that one encounters these days, this one gives the impression of being a *real* book, and one which the publishers seem to have spared no expense in producing. There are, of course, numerous text figures and photographs, most of them excellent, and even a section of colour photographs. Most striking, however, is the liberal use of white paper. Many diagrams have a whole page to themselves, and the text pages have six centimetre margins.

There are three main parts to the text. The first deals with the background to volcanology, the second covers the types of eruptions, and the third is rather a hotch-potch entitled "Theory, Cycles, Utilization and Environmental Effects of Volcanoes".

The core of the book is the section on types of volcanic eruptions, and it is here that its major strengths and weaknesses lie. Almost all of the useful parts of the book are concentrated in this section; detailed histories of individual volcanoes and eruptions. Bullard exhibits the evidence of much patient scholarship here. He has obviously tracked down and read a vast number of original references, including some very obscure ones. To take just one example, his account of the eruption of Mt Katmai in 1912 and the subsequent scientific investigations is unquestionably better than any other book in print. Many other authors have written about the same events, but they have based their accounts on secondary or even tertiary sources, thus blurring and muddying the facts. Having gone right back to the primary sources, Bullard's descriptions have a notable freshness and precision. Neither are they mere dry reviews. Bullard uses his narrative skill to present his material in a thoroughly readable, stimulating style.

Having said this, it is unfortunate that one has to look at the other, tarnished side of the coin. Bullard nowhere discusses adequately the criteria by which he recognises different types of eruption, and often seems to confuse a *type* of eruption with an individual volcano. Thus, chapter 9 on "The Strombolian Type of Volcanic Eruption" makes no mention of *any* volcano other than Stromboli. (About one-third of the chapter describes a visit made by Bullard and his wife to the island.) Similarly, chapter 10 on "The Hawaiian Type of Volcanic Eruption" deals exclusively with eruptions in the Hawaiian islands. In chapter 9, Bullard does at least begin with a few vague comments on the nature of Strombolian eruptions; in chapter 10, he prefers to discuss Captain Cook and the early history of the islands.

The book would have been strengthened by at least some discussion of modern work on classification of volcanic eruptions by granulometric analysis of pyroclastic material. This omission is characteristic of the text as a whole. The dust jacket proclaims that "Recent advances in heat flow studies and the concept of sea floor spreading and plate tectonics are incorporated to present a view of volcanology consistent with our present state of knowledge". This is emphatically not the case. In fact, the book has generally a somewhat dated atmosphere to it. Only a small proportion of the many works referenced were published in this decade. There are, indeed, two chapters on island arcs and plate tectonics, but they sit rather uncomfortably at the end of the book as rather unnecessary appendages, not well integrated with the rest of the text. They are competent enough reviews, but are unlikely to be of much value at present, when there are so many other good reviews around, and particularly because Bullard dampens any enthusiasm his readers may have for plate tectonics by implying quite clearly that he is not terribly impressed by it all.

In summary, *Volcanoes of the Earth* is an excellent source of facts on historical volcanic eruptions. As a review of modern volcanology it leaves much to be desired.

Peter Francis

Peter Francis is Lecturer in Earth Sciences at The Open University, Milton Keynes, UK.

Crystalline rocks

Evolution of the Crystalline Rocks. Edited by D. K. Bailey and R. Macdonald. Pp. ix+484. (Academic: London and New York, 1976.) £16; $35.

ALMOST half a century has elapsed since the appearance of Bowen's *Evolution of the Igneous Rocks* (1928). In that time major advances in both equipment and experimental techniques have led to a wealth of published experimental data, presenting the contributors with an unenviable task in writing a sequel to Bowen's work, within the confines of a single volume. Not surprisingly all aspects of the contribution of experimental petrology to the understanding of the evolution of crystalline rocks could not be covered, but the omissions in the igneous section, noticeably the basic and intermediate rocks, have led to a marked imbalance in the text.

The opening chapter on experimental methods offers a basic introduction for newcomers to experimental petrology. More detailed accounts of specific techniques can be found in the references cited. The choice of PT subdivisions in the metamorphic section has inevitably led to a certain amount of duplication. This has, however, resulted in some interesting insights into the differing criteria used by individual contributors in assessing the various conflicting sets of data (see Greenwood and Schreyer on the stability of Al_2SiO_5 polymorphs).

Newton and Fyfe give a comprehensive account of blueschist metamorphism (57 pages), but have rather scantily covered eclogites and granulites (10 pages). Greenwood offers one of the best sections, striking a very good balance between the major aspects of experimental petrology and its application to quantifying the intensive parameters in a range of metamorphic rocks. Schreyer has adopted a slightly different approach concentrating more on the phase chemistry aspects at high temperatures and low pressures.

The section on granitic rocks is mainly concerned with the crystallisation of haplo granitic melts. The reader's attention is drawn to the paucity of data for water undersaturated systems and the composition of the vapour phase in equilibrium with solidus reactions. In his concluding remarks, Luth has essentially critically reviewed his own contribution, by pointing out the omissions in dealing with the ultimate source of granitic melts and the volcanic rocks of granitic composition. Bailey presents a very concise review of the major aspects of alkaline rocks, delineating some of the problems in the genesis and subsequent crystallisation of the melts.

The imbalance in some of the contributions and the questionable policy of omitting certain major aspects of igneous experimental petrology will probably reduce the usefullness of this book as an undergraduate text.

J. Nolan

J. Nolan is Lecturer in Petrology in the Geology Department, Imperial College, London, UK.

Atomic and molecular processes

Atomic Processes and Applications. (In Honour of David R. Bate's 60th Birthday.) Edited by P. G. Burke and B. L. Moiseiwitsch. Pp. x+533. (North-Holland: Amsterdam, New York and Oxford, 1976.) Dfl.165; $65.95.

THIS book forms a remarkable tribute to the scientific work in atomic and molecular physics over the past 40 years of David R. Bates' life. The scene is set in a perceptive and affectionate tribute to David Bates on his sixtieth birthday by Sir Harrie Massey, who begins by recalling his first meeting with Bates when, in 1934, he went to Queen's University, Belfast, as Lecturer in Mathematical Physics. Bates was one of the group of able young men from Ulster attracted by Massey to work in theoretical physics. The work based on their cooperation first at Belfast, then at University College, London, and later, also, in the school founded by David Bates when he returned as Professor to Queen's University in 1951, represents a large part of the progress made over this period in the study of atomic and molecular processes. It is indeed a striking example of the influence of the great leader and teacher in science that so many of the authors of articles in this book have been students at Queen's University. All of them have more or less close connections with either University College, London or Queen's. In this respect, it is not surprising that the book conveys an extraordinary sense of family.

Apart from the introductory tribute by Sir Harrie Massey, the thirteen articles which make up the book form a highly readable account of the present state of progress in the study of atomic processes. The first three articles deal with the Earth's atmosphere: M. Nicolet on Stratospheric Aeronomy, J. C. G. Walker on the Upper Atmosphere, and M. B. McElroy on Problems in Atmospheric Pollution. M. Nicolet considers the principal reactions first in an oxygen atmosphere, then in turn adding hydrogen, nitrogen and halogens. The theoretical problem of stratospheric ozone is resolved and the situation concerning minor constituents described. J. C. G. Walker provides an admirable summary of present knowledge of the chemistry of the E and F regions, stressing the importance in the understanding of the phenomena of dissociative recombination of molecular ions as the process for removing ions and electrons, as first suggested by Bates and Massey in 1947. M. B. McElroy, in an excellent account of man's impact on the global environment, pays tribute to the classic contribution of Bates and Witherspoon (1952).

The theme of molecules in interstellar space is taken up by A. Dalgarno, who deals with formation and destruction mechanisms for CH and CH^+. The problem posed for the abundance of CH^+ by the existence of molecular hydrogen in interstellar clouds, is considered. The process of di-electronic recombination of special interest in connection with the solar corona, is the subject of a theoretically interesting treatment by M. J. Seaton and P. J. Storey.

The remaining eight chapters of the book are devoted to an authoritative series of reviews of some of the main fields of study in atomic and molecular processes. Pioneering contributions were made in many of these by David Bates, and he has continued to contribute to them up to the present day. Photoionisation of atomic systems and electron scattering by atoms are the subject of masterly reviews by P. G. Burke and M. C. McDowell. B. L. Moiseiwitsch and A. L. Stewart contribute chapters, respectively, on negative ions and oscillator strengths. There is a thought-provoking chapter on computational methods by I. C. Percival.

The book concludes with three chapters on ionic recombination and atomic collision processes by M. R. Flannery, R. McCarroll, K. L. Bell and A. E. Kingston. Throughout this series of chapters, it is fascinating to follow the increased understanding which has come from the use of atomic models of increasing sophistication and from the growth of computational facilities. Another interesting aspect is the balance of success in appropriate régimes of quantal semi-classical and classical methods.

The editors are to be congratulated on the volume of work which they have brought together. The presentation is of uniform clarity and free, as far as I could detect, from all but the most trivial misprints. It must be a great joy to Professor Bates to have gathered together for him by this group of his students, colleagues and friends a description of a scientific edifice which he helped to found and did so much to build. Apart from this celebratory aspect the book is to be recommended as providing an admirable description of the state of the art in the study of atomic processes, which are of such increasing importance in a growing number of fields of interest in contemporary physics.

Earth pictures

Mission to Earth: Landsat Views the World. By N. M. Short, P. D. Lowman, Jr, S. C. Freden and W. A. Finch, Jr. (NASA: Washington, DC, 1976.) $14.

LANDSAT, launched in 1972, was the first of a generation of unmanned satellites dedicated to repetitive surveillance of the continents and adjacent coastal waters to gather data for a variety of practical applications in Earth Resources disciplines, such as cartography, geological mapping, mineral resource evaluation, water inventory, coast and wetlands management, land-use assessment, and so on.

The above publication contains some 400 colour plates of outstanding Landsat pictures of areas all over the World, compiled and selected from more than 100,000 processed and reconstructed images, obtained during its first four years of operation. Each plate is accompanied by a carefully prepared narrative caption, summarising notable features. Taking into account that these photographs were available anyway from their Earth Resources program, it can only be warmly welcomed that NASA has made this selection of outstanding pictures available to the general public at the comparatively low price of $14. These photographs are likely to be of great interest not only to the various resource specialists amongst the appropriate Government authorities in the various countries concerned, but also to the serious teachers and students in geography, geology and allied disciplines, and to the general public with an interest in travel and geography.

Copies and slides of individual photographs are also obtainable, as well as free copies of an educational supplement, the *Educator's Guide,* which provides a general description of the Landsat program, the operation of the satellite and an explanation of remote sensing and imagery with suggested classroom uses of the material.

obituary

W. Grey Walter

DR W. GREY WALTER, who had an international reputation for his work on brain function, died suddenly on 6 May 1977, aged 67.

William Grey Walter—Grey to his many friends—was born in Kansas City in 1910 of an American mother and an English father, Karl Walter, editor of the *Kansas City Star*. The family came to London in 1917 and Grey went to Westminster School and then to Cambridge where he obtained a first in natural sciences in 1931, and did postgraduate work on nerve physiology with Professor (now Sir Brian) Matthews.

In 1935 he joined Professor F. L. Golla at the Maudsley Hospital and started the work on brain function that was to occupy all of his working life. In 1936 almost by chance an opportunity arose to record the electrical activity of the brain (electroencephalogram, EEG) of a patient with a cerebral tumour, and the characteristic low frequency (1 Hz) activity was discovered. This work opened up a new era in the detection and localisation of brain lesions. using the EEG. During this same period Grey was recording the EEGs of many epileptic patients and showed that many of them were abnormal *between* fits.

In 1939 Golla moved to Bristol to open a research laboratory and clinic called the Burden Neurological Institute and took Grey Walter with him. Here Grey was able to expand his work and was responsible for many new developments and discoveries. He made the first instrument in Britain for electro-shock therapy (1939) and was co-worker in its early use; he opened up the first clinical EEG department in Britain (1940); he developed the first portable electroencephalograph and the first low frequency automatic wave analyser (1942); and he developed electrode probes for recording deep within the brain during neurosurgical operations (1941).

In 1943 he discovered the theta rhythm; and later used the stroboscope to activate brain abnormalities in epileptic patients, triggering the flash from the brain activity—a particularly effective form of bio-feedback. It was about this time that he investigated the relationship between the EEG and mental imagery; in 1947 he published a paper on the effects of sensory stimuli on the EEG. In the same year he was awarded the ScD from Cambridge University for his outstanding scientific work. Although a physiologist, his work was often closely related to clinical practice and in 1949 to mark the importance of this aspect of his work he was awarded an honorary MD and made honorary Professor of the University of Aix-Marseille.

At the turn of the decade Grey Walter was attracted to the new science of cybernetics which gave opportunity of rich cross-fertilisation of many disciplines. He developed several fascinating models of behaviour of which the mechanical tortoise *Machina speculatrix* was the most famous. In his book *The Living Brain* (1953) he drew together many aspects of brain science. Its value was not so much scientific (as most of the work had been published elsewhere) but as one of the first successful attempts to present such concepts in a readable form to the non-scientist.

From the beginning Grey Walter was fascinated by the concepts of Pavlovian conditioning and its application to learning processes. Many and varied were the experiments on this theme throughout the years using the EEG as an indicator of brain function in behaviour, but it was not until the technological development of averaging devices in the early '60s, enabling brain responses to sensory stimuli to be extracted easily from the background EEG, that the crucial discovery was made. This was the observation that changes of cortical potentials occur as a person having been prewarned by one stimulus makes a response to a second. This Grey Walter called the contingent negative variation (CNV) and published the work in *Nature* in 1964. Grey discovered the CNV not with the open mind said to be used by scientists but by a stubborn prejudice and persistent, perceptive searching for what "had to be there."

By a cruel and ironic stroke of misfortune, Grey Walter was involved in a road traffic accident in 1970 and suffered severe brain injury. He was unconscious for about three weeks but gradually made a remarkable recovery. He was appointed Emeritus Consultant when he retired from the Burden Neurological Institute in 1975. In the same year the EEG Society, of which he was a founder member, struck a special Grey Walter Medal and presented the first award to Grey Walter himself for his outstanding achievements. In 1974 he was awarded the Oliver-Sharpey prize of the Royal College of Physicians.

In these days of high technology it is difficult to realise the primitive nature of the scientific tools available in the 1930s. The electroencephalogram as recorded from scalp electrodes is about 50 microvolts peak to peak and has a frequency range from DC to about 100Hz. Even today much care is needed in order to record the EEG in a hospital environment where electrostatic and electromagnetic interference causes many problems. When Grey Walter started, the balanced (push-pull) amplifier had just been developed by Tonnies and the electronic components needed for the amplification of the low frequency brain activity were somewhat bulky when available. All the early equipment was made by Grey himself and had to be treated with loving care. Much of his early work was done using a smoked drum as recorder and many disagreeable hours must have been spent coating the paper; not until 1939 did he obtain a three channel inkwriter that gave long uninterrupted records. Much of this technological development occured during the war years when shortages of equipment were very acute.

The main significance of his early work was not technological, though this was impressive enough, but the introduction into clinical medicine in this country of a unique method of studying the *functioning* brain. Even with the introduction of the EMI scanner and computer techniques thirty years later the EEG remains the only non-invasive method of observing the brain in action on a second to second time scale. Perhaps not surprisingly, the application of these techniques to patients by a physiologist was not always welcomed by the medical profession and even today there are only one or two scientists without medical qualifications reading clinical EEGs.

But what of the man? Grey was generous and helpful to others, especially young scientists, but sometimes his behaviour seemed arrogant, especially with senior colleagues, in the way of many scientists when they know (or think) that they are right. The publication of the CNV was delayed for about a year while he made sure that it was not an artefact due to eye movements. Even after the publication, many groups throughout the world doubted whether it was a cortical event; Grey's attitude was firm, 'Let them spend time doubting, it will take them longer to catch us up.' He was unconcerned about money and in the 1950s was content with such a low salary that the income tax inspector did not believe his declared income. Yet over the years Grey obtained hundreds of thousands of pounds for the equipment and work at the Burden Institute. I think that he considered that to be able to work on brain research was a privilege that had to be paid for and I am sure that he would have continued working for nothing if the necessity had arisen. Work was a major passion in his life and he would spend many, many hours in the laboratory trying out new ideas often without any real lead to follow, persisting in the belief that discoveries are made in the laboratory and not at the desk or committee meetings. It is a pity that there are so few like him.

R. Cooper

Frank Green

Dr Frank Green, CBE, MD, who died on 30 April 1977 in his 77th year, had lived his professional life as a research administrator. From 1929 to 1955 he served the Medical Research Council rising through the various grades from Medical Officer to Principal and at the end of his period was Publications Editor. Their special reports were perhaps appropriately named "Green" books.

He worked under a succession of Secretaries from Sir Walter Fletcher and Sir Edward Mellanby to Sir Harold Himsworth. In the pre-war period of his MRC service the annual budget, allocated directly by the Privy Council, rose from approximately £150,000 to nearly £200,000. The organisation remained small, intimate and friendly and its relationships with a small band of research workers were personal, smooth running and inexpensive. Frank got to know them all and his wife Joyce acted as a charming hostess to many of us.

The MRC then occupied a pleasant old Georgian house at 38 Old Queen Street and the Council acted with an ease of judgement and the lightest of control. Research was still cheap, equipment often home made at laboratory benches, and grantees were trusted to spend their modest (often three-figure) allocations to the advantage of their experiments, which were, in those days, usually pursued with their own hands, with very limited technical help. When the War ended in 1945 the Treasury began to intervene in the allocations which in 1946 reached half a million pounds, and were subsequently multiplied to two million by 1955. The MRC was now growing into a larger and less informal body, personal contacts became less easy to maintain, and the channels of communication became more complex.

Frank then side-stepped into the growing Wellcome Trust thus coming back into a much smaller organisation, in which he was in continuous daily contact with the chairman, Sir Henry Dale, the doyen of medical science of our era. The Wellcome funds at that time were limited to a few hundred thousand pounds and decisions of great responsibility fell largely to Dale's admirable scientific judgement combined with Green's personal knowledge of research applicants.

The allocations in those days were mainly to provide for costly equipment such as electron microscopes and many new laboratories of which the Medical Schools were in dire need. Indeed with out help from the Wellcome Trust medical research in our Universities in the immediate post-war years would have been severely hampered. Frank as the Executive Secretary was thus a trusted and key figure approached by everybody in need of supplements. Extrapolating backwards through his experience of the MRC he had indeed been a key figure in facilitating almost the whole development of British medical research from 1930 into the present era. His experience as Editor in the MRC gave him a capacity to work hard on drafts and produce his reports in impeccable English.

He was frequently invalided, often crippled by bronchitis and asthma. He worked to the limit of his capacity until recurrent illnesses each winter made it difficult for him to continue with his growing responsibilities while other physical disabilities also made him less mobile. When he relinquished his advisory services to the Wellcome Trust he gave part time services to the Science Committee of the growing British Heart Foundation. Once again his knowledge of personalities and his experience in judging applications helped to create a system in which the expertise of the various committees was always supplemented by consultation with appropriate experts in collateral fields. He thus epitomised in himself the ethics of research development and support based on the highest judgement of achievement and an intimate knowledge not only of the applicants and their sponsors but also of suitable referees.

He endured a long physical illness with patience supported and nursed by his loyal and devoted wife who always welcomed visits from their old friends.

Sir John McMichael

M. F. Lucas Keene

Professor Mary Frances Lucas Keene, doyenne of British anatomists, was born 15 August 1885 and died 9 May 1977. Her professional life was dedicated to the Royal Free Hospital School of Medicine (formerly London School of Medicine for Women), to the interests of the medical profession and the enhancement of the status of women therein. A brilliant undergraduate in the School she attracted encouragement from Stanley Boyd and F. G. Parsons and after adopting a career in anatomy was later influenced by F. Wood Jones. She graduated MB, BS in 1911 and joined the School's anatomy department to serve it with distinction as Lecturer in Embryology and Senior Demonstrator of Anatomy (1914), Lecturer and Head of Department (1919) and University Professor (1924-51). On retirement she was elected Emeritus Professor in the University of London.

Her principal researches were neurological and produced meticulous studies of the posterior commissure, the subcommissural region, muscle spindles and intramuscular sensory organs: her pioneer investigations of the process of myelination earned the award of the DSc of London University.

Lucas Keene was exceptionally endowed with powers of organisation and judicial assessment and was wholeheartedly committed to duty. These qualities gained early recognition and were inevitably empanelled in the general service of School and University. Without remission of departmental commitment she accordingly assumed and discharged with notable success an onerous burden of scholastic and administrative business which involved, during the Second World War, added responsibility for the School's migrant preclinical departments and the reconstruction of its bomb-devastated premises.

Her integrity and profound common sense fortified by her personal dignity and charm, redounded to her School's prestige and engendered wide extramural appreciation of her judgement and counsel. Her achievements and services were fittingly recognised by her election to the presidency of the School of Medicine (1956-74), of the Anatomical Society (1949-51) and of the Medical Women's Federation (1946-49), to vice-presidency of the Medical Protection Society (1929-77), to the livery of the Worshipful Society of Apothecaries (1952) and to the Fellowship of the Royal College of Surgeons of England (1956).

4 August 1977

Test ban: new hopes, new hurdles

DISCUSSIONS on a nuclear test ban covering explosions in all environments and of all yields have dragged on for very nearly twenty years, so the optimistic noises now being made following the Geneva talks between the Soviet Union, the United States and United Kingdom should not be misinterpreted as more than a ray of hope. Even so, prospects look better now than at any time since 1963 for this major arms control measure to be brought to a conclusion—if the thorny issue of peaceful nuclear explosions can be settled.

It was in 1958 that the first international scientific discussions were held on monitoring a test ban treaty, and these, together with a growing public concern about radioactivity, led to a 1963 treaty, widely but not universally signed and ratified, which outlawed test explosions in all environments except underground. At the time it seemed that it was only modest disagreement between the United States and Soviet Union concerning on-site inspections and unmanned monitoring stations which stood between the negotiators and a truly comprehensive ban. In hindsight, however, it looks most unlikely that the United States would have been prepared to go the whole way in 1963, as ratification might have been impossible in the face of a very strong nuclear lobby.

For the first few years after 1963 a comprehensive treaty seemed out of the question politically and militarily, although seismic monitoring methods were steadily improving. Then, when seismology seemed to be incapable of offering any spectacular further developments, worries started to be made known about the possibility of evasion (by firing a shot shortly after an earthquake, for instance). And the growing vigour of the Soviet programme of peaceful nuclear explosions caused some to wonder whether military tests might be made under the cover of civil engineering. The Indian explosion in 1974 helped convert many more to this point of view.

Against this background the United States and Soviet Union made a rather odd move by agreeing on a bilateral treaty restricting tests to be below a yield of 150 kilotons. This agreement was widely regarded as a poor substitute for a comprehensive treaty (its ratification hearings are still being held in Washington) and as a means of holding up progress on a comprehensive treaty for many years. But this was before President Carter.

It is clear that Carter attaches considerable importance to progress on a test ban. The team that the United States is fielding at Geneva is remarkably strong and contains several of those who were involved in the 1963 negotiattions and who have showed continued interest in fostering arms control. For the moment, at least, the Arms Control and Disarmament Agency is in the driver's seat.

The meetings so far, in embassies, have been outside the normal Geneva disarmament forum of the United Nations Conference of the Committee on Disarmament (CCD), but if last week's optimism prevails, at some stage the matter will presumably be passed to the CCD where a more multinational analysis can be made of the technical and political issues. There are, however, still stumbling blocks. The first is that the US Congress would have to ratify the treaty, and although the nuclear weapons lobby in Washington is not what it used to be, the Energy Research and Development Administration is not likely to give away one of its birthrights without much agonising.

Second, it is by no means yet clear that the peaceful-nuclear-explosions issue can be resolved. The United States has all but abandoned its Plowshare programme and is likely to ask the Soviet Union to do the same to eliminate suspicions of misuse. The Soviet Union may find this unacceptable—a large portion of its Geneva delegation consisted of peaceful-explosions experts, which shows the importance it now attaches to these operations.

If the Soviet Union really wants to go ahead with its programme then the United States should not be allowed to get away with an excuse for stepping back from a treaty. Maybe the United Kingdom delegation should be hard at work trying to get an international agency to provide the necessary explosive. This idea has been talked about in recent years at the International Atomic Energy Agency but as yet no-one has asked them to look at the Soviet problem, which is undoubtedly a very complicated one. This is a job the United Kingdom should take upon itself. ☐

What kind of food policy?

Colin Blythe and **Howard Rush** examine whether nutritional goals can be a basis for agricultural policy

PARTICIPANTS at a number of recent conferences in Britain have tried to clarify the links between nutritional requirements, food production and supplies. Titles of meetings reflect the interest: 'People and Food Tomorrow', 'Towards a Healthier Britain' and, most recently, 'Nutritional Aspects of Food and Agricultural Policy in the United Kingdom'. All have raised a number of scientific, ethical and practical problems, and it has become apparent that until these are resolved little progress towards one coherent policy, integrating nutritional considerations, food supplies and agricultural production, seems possible. It is even argued that British policy makers remain unconvinced of the need for such a policy. What are the main arguments?

The possibility of malnutrition in some low-income groups has occasioned some concern. Clinical evidence of deficiencies is not common, however, except in certain well-defined groups, and where deficiency malnutrition exists, it is seldom due to simple poverty. Low levels of vitamin D and associated rickets occur in parts of the UK Asian community. Osteomalacia and vitamin C deficiency (not necessarily together) are found in a proportion of the elderly. Iron deficiency anaemia is said to affect about 10% of women in the UK, and folate deficiency (showing as megaloblastic anaemia of pregnancy) has occurred recently in about 2.5% of women. Deficiencies of other micronutrients may occur but the number of affected individuals is small.

In contrast, reports and papers dealing with the 'diseases of affluence' are growing more numerous; since 1970 nearly twenty reports have come from national bodies on the subject of coronary heart disease alone. As well as cardio- and cerebro-vascular disease, the list includes diverticulitis, appendicitis, constipation, certain forms of colonic cancer and, with its numerous sequelae (backache, arthritis of knees and hips, gallstones, renal failure and fallen arches), obesity.

The consensus of opinion in these reports is that some aspects of Western diet are partly responsible for the present levels of these diseases. Most conclude that wholesale changes in diet are necessary before the major causes of illness and premature death are brought under control. The US Senate Select Committee on Nutrition and Human Needs, under Senator McGovern, has recently promulgated a set of Dietary Goals: these include a reduction of total fat intake (within which there should be a decrease in the proportion of saturated fats and an increase in the proportion of polyunsaturated fats), a reduction in dietary cholesterol, sugar and salt, and an increase in consumption of complex carbohydrates. Sweden has had a Diet and Exercise Programme, incorporating similar goals, since 1972. Norway recently announced its intention to use pricing policy as well as education in an attempt to influence eating habits.

Evidence contested

Unfortunately, the factual evidence underlying goals of this type is contested. Disagreements over both causation and remedial measures are one reason. They have meant that the connection between diet and disease is not yet strong enough in the minds of UK policy makers for them to accord nutrition a priority in economic decisions. But having no policy amounts, in reality, to a policy of letting things drift, something which is clearly unsatisfactory. And the World Health Organisation said in 1969 that the incidence of certain diseases (coronary heart disease, for example) had reached almost "epidemic proportions".

The issues of causation may not have been resolved by clinical procedures, but then many of the tests needed to establish a causal relationship can only be performed on live human beings, and large numbers of them at that. Absolute proof may be years in coming. In the absence of absolute proof, this demands the exercise of scientific judgment based upon the best information avilable. Whether to wait for final proof (one way or the other), or whether to advise action now, is something which presents nutritionists with difficulties of judgment and also of conscience.

Camera Press

In Britain, the existing government role concerning diet is primarily one of monitoring, testing and education. In addition, a web of legislation governing food standards, additives, labelling and advertising has evolved largely on an *ad hoc* basis. Policy questions, such as whether Britain should or could feed itself, usually turn upon issues of security of supplies and the balance of payments. Seldom, if ever, are variations in food supplies or self-sufficiency levels related to their possible effects on the nutritional status of the population. Nor would it seem that nutritional considerations have prompted recent government interventions in food prices. Mollifying consumer unrest, assisting the economically disadvantaged and dealing with farm surpluses have been of greater concern.

The lack of nutritional reasoning behind adjustments to food supplies and prices does not, however, mean that such moves lack nutritional impact. EEC policy, for instance, is to reduce the price of certain items currently in over-supply, like butter, in order to stimulate demand, increase consumption and clear the surplus. Beyond boosting consumption artificially, this produces a secondary effect: the tendency to maintain isocaloric balance means that, as consumption of some foods rises, consumption of other items falls. In other words, by manipulating food prices for basically agricultural purposes, governments can apparently exert an effect on eating patterns and, unwittingly, on nutritional status. As recent EEC policy has sought to encourage consumption of some items which epidemiological evidence has linked with disease, the anxiety of many nutritionists to see nutritional criteria built into food policy becomes understandable.

Basis for policy?

But if the factual evidence underlying nutritional goals is controversial, so is the advisability of using them as the basis of policy. Government intervention in dietary matters is a hotly contested issue. Among nutritionists a sizeable lobby believes that the scale of diet-related disease is such as to justify a far more radical approach to public health. This group would like to see

---

Colin Blythe is at the Department of Nutrition, Queen Elizabeth College, London.
Howard Rush is at the Science Policy Research Unit, University of Sussex.

pricing and educational measures employed as part of a coherent policy of trying to prevent ill health, rather than attempting to cure the results of unwise living. A shift to preventive medicine is economically attractive. Although few figures are available for Britain, recent estimates put the total costs to the US economy of heart disease and other diet-related illness at between $30–35 billion annually. Costs to the UK economy must also be considerable. It may be that prices of alcohol, tobacco and some food items should more accurately reflect the community health costs incurred by their overconsumption.

A national programme of preventive medicine would almost certainly involve individuals assuming greater responsibility for their own health and basing their actions on adequate information. Attempts to educate the public on dietary matters, however, have a poor record of success. If changes are to occur in consumption levels public education may need to be reinforced with food price adjustments. Such procedures would have to be thought out with great care. Some evidence exists for suggesting that subsidies do not always benefit target groups as intended. So if taxes are also to be used to persuade consumers to alter their habits, steps will have to be taken to ensure the adequacy of diets among low-income groups.

Opponents of blanket government measures believe that improved screening and diagnosis are all that is required. After diagnosis, those at risk can take remedial action and those unaffected can escape being troubled or inconvenienced by wholesale measures. This view contends that, although nutritional needs can be assessed case-by-case, prescribing average requirements for entire populations on present knowledge is premature, and might even endanger some people's health. In discouraging overconsumption, it is asked, how is discrimination avoided against those who are not overconsuming, or those who, if they are at risk at all, may be at risk from under- rather than over-nutrition? And even if causation could be proved and remedial measures agreed, what of the freedom of individual choice? Is it for governments to coerce people into taking measures for their own good?

In the end, other factors may dictate the best course of action—the state of the economy, for example, or the adequacy of diagnostic facilities and personnel. Identifying every individual at risk of heart disease or stroke would involve a major programme of screening, with those placed in the 'at risk' category being examined at, say, yearly intervals, the rest perhaps every four or five years. Such a programme would add greatly to the costs of a Health Service already widely regarded as economically burdensome.

Disagreements

This discussion of means obscures the fact that no policy maker can be expected to act until a basis for action has been agreed. Unfortunately, there are strong disagreements over appropriate remedial measures. One example of conflicting advice to the government lies in recent evidence to the UK House of Commons Expenditure Committee considering preventive medicine. In this, the British Dietetic Association suggested that "a moderate reversal to diets in which bread and potato consumption are *increased* would be an advantage"; the British Medical Association felt that "the right diet for optimal weight was relatively high in fat, high in protein and *low* in carbohydrates". Such advice is just as confusing to individuals who wish to follow sensible eating regimes.

The quality and relevance as public guidelines of some other information is also open to doubt. Tools long accepted for evaluating nutritional status, such as the Recommended Daily Intake (RDI) tables, have begun to be questioned. Should the RDIs relate to a level of intake designed to secure optimum health (a concept in itself difficult to define), or to a level necessary to avoid the onset of illness? If the latter then, given that nutrient requirements vary not only for age and sex but also for bodyweight and metabolic type, illness for whom? The question of how much information now available can usefully be applied in constructing diets is also relevant. For example, is the RDI of 30 mg vitamin C per day for an adult to be secured by eating one tomato, or two? If minimum nutrient requirements cannot be assessed except on a case-by-case basis, if the notion of an 'optimal' intake is unscientific, and if the RDI tables offer no guidance on the designing of meals, what useful purpose is served by such information?

All these general problems have meant that governments have received little in the way of useful advice regarding the effect of agricultural policy on nutrition, although the fact that agricultural policy can influence nutrition is not seriously disputed. Clearly, when the major problems within nutrition are sorted out, it will be time for some cross-fertilisation to take place between disciplines. At a conference organised by the Nutrition Society in Reading recently, one example did emerge of the type of thinking that may be required to bridge the agriculture/nutrition gap.

In it, Professor W. Holmes briefly suggested some changes and problems facing UK agriculture if food goals outlined by the US Senate and others are to be realised. For example, an increase in the contribution of bread grains, vegetables and fruit to the diet, and a reduction in the intake of animal products (especially animal fats), might require a corresponding increase in the arable area and a reduction in the use of grain for animal feed. Though noting that such a change was technically feasible, he pointed out the considerable effects on the cost and profitability of farming and on the ancillary industries. A detailed study of the complex components within the farming community and of the incentives and advice necessary to achieve improvements was necessary, before any attempt to implement a food policy was likely to be successful. □

Research on research

The UK Social Research Council (SSRC) has approved a grant application from the Science Policy Research Unit (SPRU) of the University of Sussex to assess the criteria used by the Science Research Council (SRC) for capital projects in basic science. Chris Sherwell reports.

IT WAS perhaps inevitable. Certainly an investigation of the funding of big science in Britain had everything going for it. Hard economic times produce whipping boys, and in Britain's research community it is big science. Likewise growing disciplines generate new fields to conquer, and for the social sciences in Britain science policy is indisputably one of them. Last week's news that the SSRC is funding research on the SRC's funding of research should therefore have been no surprise; in fact the fall-out may be more than inconsequential.

No one is denying that the SSRC has the right and duty to sponsor policy research. And no one doubts the SRC is a good candidate for consideration in the field of science. It takes a major (54%) but now declining share of the £216-million science budget doled out to the research councils. Similarly, with high energy physics, astronomy, space and radio science—the traditional areas involving large capital-spending projects—consuming some 60% of that share, big science is a natural object of attention. Indeed, in annual spending terms it is comparable to research and development on the fast breeder reactor or, in its day, on Concorde.

But there are some raised eyebrows, both inside and outside the SRC. Scientists who privately frown on some of the projects sponsored by the SSRC are never too difficult to find, of course; and the SRC cannot comment officially on projects sponsored by other research councils. But some reactions last week were sceptical. The director of one big science laboratory said rather obviously that he would have preferred to see the money going to his own work. Others, however, doubt the motives behind the proposed research. There were also questions about whether the project could even be done.

The proposal, a year in gestation, is contained in a document running to 18 pages with 5 appendices. It was submitted by Dr Roy Turner and Mr Keith Pavitt of SPRU and Dr Norman Dombey, reader in theoretical physics at Sussex, to the SSRC's political science committee. The SSRC approved the grant application in principle almost three weeks ago. The amount involved is £26,345 over two years, and the team is now looking urgently for a scientist and a social scientist so that the work can begin in October.

Their case for the study is simple. There is not as much work in Britain on the problems of science policy as there ought to be compared with North America. The SRC disposes of a large sum of money on basic research, and now faces hard choices distributing resources between big science and the rest of science. Yet, says the team, it is not known whether there is any technological benefit from, say, a high energy physics programme which could not have been achieved more cheaply by direct industrial research; nor are there guidelines on what proportions of funds should be allocated to fields in which there will be no foreseeable technological benefit.

The team says it has four aims. The first is to assess the research of six SRC centres in terms of certain criteria. The six centres are in high energy physics (CERN, Rutherford and Daresbury) and in astronomy (the Isaac Newton telescope, the Nuffield radio astronomy laboratories and the Mullard radio astronomy observatory). The criteria are 'intrinsic' (by which is meant the merit of the science and the researchers, and the benefits to other fields of science); 'educational' (the benefit to those who teach and those who work in other scientific fields); and 'technological' (the long term and short term application of the results and methods of research).

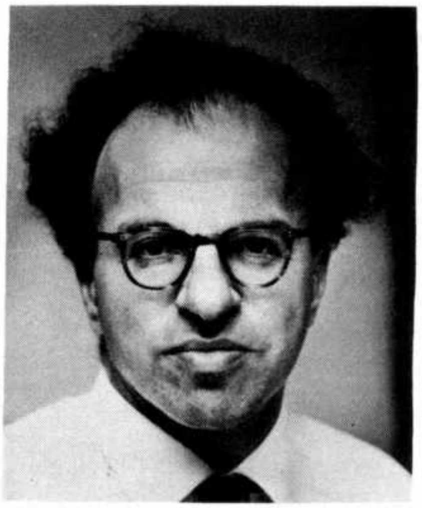
The team expects to spend two-thirds of its time on this aspect alone. The rest will be spent comparing the actual performance of the centres with their original justification, applying what is learned to proposals to set up new centres (the team has in mind the high powered laser facility and, though it is not in the SRC's remit, JET, the European fusion project), and finally considering British and international practice in funding big science.

In its proposal the team explains how it plans to proceed, and it is here that the difficulties may emerge. They will assess the research by speaking to scientists in the field, circulating questionnaires and examining published papers. The original justification for the centres will be

Bondi goes to Energy

AS WIDELY expected, Sir Hermann Bondi is to replace Dr Walter Marshall as Chief Scientist in the UK Department of Energy. For the past six years Sir Hermann has been Chief Scientific Adviser at the Ministry of Defence. He goes into the Department of Energy with no strongly expressed views on the record concerning choice of reactor, the balance between nuclear, hydrocarbon and renewable energy sources, or the wisdom of a fast-breeder programme; he freely admits that he has a lot to learn.

Sir Hermann looks back on his time at the Ministry of Defence with satisfaction; in part his role has been as a person to whom anyone could turn for disinterested and friendly advice and criticism. But he has always preached mobility—sometimes to a rather hostile audience within the civil service—and he clearly practises what he preaches. In his own words, the defence post is the "fourth good job I have thrown up". The others were a lectureship and fellowship at Cambridge, a professorship at Kings



College, London, and the directorship of the European Space Research Organisation. He admits there is a touch of masochism in this, but he felt he was getting too comfortable at Defence and was no longer an outsider. It will be interesting to see whether the Ministry of Defence has the courage to appoint another outsider.

learned, the team says, by interviewing those involved in the decisions (like Sir Alec Merrison and Sir Denys Wilkinson in the case of Rutherford and Daresbury and Sir Martin Ryle in the case of Mullard), from published sources (in the case of CERN) and if possible through access to original documents.

But the team is likely to face a critical problem over access to SRC documents. When Mike Gibbons and John Hartland did their study of CERN for the old Council of Scientific Policy (CSP)—a study the team mentions—the SRC gave special dispensation because the study was confidential to the Council; when Margaret Gowing sought SRC documents for her study of CERN on behalf of CERN, the SRC was prepared to allow access but the Department of Education and Science refused under the thirty-year rule. On that history, access is likely to be denied to the SPRU researchers.

The team does not see possible denial of access as a special difficulty. But Gibbons thinks otherwise. Not only did it take him and Hartland two years to do their study, which was of one centre, not six plus two new ones; they also found the original documents essential in providing what he calls a "well constructed net", the holes of which could be plugged with the help of interviews. Only with the documents could they appreciate just how much memories failed with time and how beneficial hindsight could be.

Whether or not the research yields controversial findings, the fact that it is going ahead at all has certainly provoked interest. The SSRC has some £25,000 at its disposal for science policy studies; this used to be in the hands of the CSP but was transferred to the SSRC when the Advisory Board for the Research Councils (ABRC) began. This award to the SPRU team means that other applications are denied. That is nothing new, except that, in going to one large project, it is ironically favouring 'big science policy' proposals at the expense of others whose merit may be as clear. More interestingly, and particularly as the research is about the SRC, the SRC is certain to have seen a copy of the proposals at an early stage and to have passed a verdict on it.

Two factors indicate why the SRC might be unhappy about it. One is the precedent of the Gowing case: lack of access is bound to reduce the value of the research. The other is its natural misgivings about the quality and partiality of science policy research, using anecdotal evidence or not. Indeed, Norman Dombey's own article on CERN, in *The Times Higher Education Supplement* earlier this year, is unlikely to have endeared this project to the SRC. And Keith Pavitt's views on the use to which Britain's scientists and engineers are put (typically, into aircraft, nuclear reactors and weapons instead of motor cars and machinery) won't have helped.

The topicality of the subject may have assisted the SSRC in reaching a decision. But one suggestion being put about last week, which could not be confirmed, was that the SSRC's political science committee regards its support for the SPRU proposal as a test case in its efforts to establish itself as the body sponsoring research that monitors decisions in government. The project, it was suggested, is a useful addition to the pressure for a lifting of the thirty-year rule.

As far as Dr Saul Rose, the committee's chairman, is concerned, there are bound to be differing views of its support for the project, as there are for much of the work it sponsors. As for projects that could "come up against a stone wall" because of lack of access, it was always hoped that something could be worked out; in any case projects were monitored, and could be called off or perhaps reshaped if they were unlikely to achieve the intended aims.

In the end, though, the project will be judged by its results. No one wanted to anticipate those last week, or to predict their likely impact. But one former high energy physicist privately expressed his reservations. The big science community in Britain, he said, was now highly sensitive to criticism after the financial battering of recent years. Though prepared to admit that the findings might be interesting, he couldn't see what useful purpose the project would ultimately serve. □

Reactor choice: last lap looms

The final and most important phase of Britain's tortuous debate over which type of thermal nuclear reactor should follow the existing Magnox generation is just beginning. Last week the Department of Energy (DEN) published extracts from the assessment made over the past nine months by the National Nuclear Corporation (NNC) of the three thermal reactor systems under scrutiny—the Pressurised Water Reactor (PWR), the Advanced Gas-Cooled Reactor (AGR) and the Steam Generating Heavy Water Reactor (SGHWR).

At the same time the Health and Safety Executive published an account from its Nuclear Installations Inspectorate (NII), responsible for nuclear safety, of its study of the generic safety issues of PWRs. And the DEN also made available a summary of the discussions on nuclear energy policy which emerged at the closed weekend seminar it held in May.

The nuclear industry, the customers, the politicians and others are expected to digest the contents of the massive NNC and NII volumes during a quiet August; discussions in September may then allow the matter to be put before the Cabinet for collective decision sometime in October. Mr Anthony Wedgwood Benn, the Secretary of State for Energy, for one, is looking forward to an interesting debate.

The NNC report says a decision has to be taken now both about the reactor systems and about actual orders "if the nuclear power option is to be maintained in a meaningful way". It says categorically that "there is no case for the adoption of the SGHWR" because there could be no operational experience of commercial sizes for a decade, there is no chance of exports and it is the most costly of the three.

Over the PWR and AGR, the report offers three options: continue with AGR, do not adopt PWR; adopt PWR, finish the current AGR programme but don't add to it; and adopt PWR, continue with AGR. The NNC says it cannot advise the first course because it would be rejecting important export opportunities; to be grasped, moreover, these require a decision now. The second course, it says, would help exports and lead to "the cheapest available electric power for Britain", but construction of the first PWR could only start in 1980; for the course to be acceptable, ways must be found of "maintaining the confidence and enthusiasm" of those laid off by the lack of AGR work.

The third course offers the advantage of keeping open an option, but has the disadvantage of dividing available resources. "In practice", the report suggests, "it is not likely to be sensible to maintain an ordering programme for two systems beyond the early 1980s". The summary concludes that the early adoption of the PWR would have to be supported by a domestic ordering programme of more than one reactor, and that an AGR station would have to be ordered and built, if the purposes of the choice are to be achieved.

The choice of thermal reactor was also the subject of a session at the nuclear policy seminar. Although Sir Alan Cottrell, former government science adviser, disagreed, both Ned Franklin of the NNC and Walter Marshall, the DEN's former chief scientist, thought safety arguments were not a significant factor in the choice, a point borne out by the NII report, which concludes that "there is no fundamental reason for regarding safety as an obstacle" to choosing the PWR.

One interesting contribution to the seminar came from Sir Hermann Bondi, however, whose appointment to the DEN's as chief scientist was confirmed last week. It was very likely, he said, that the first major accident would be with a PWR because of their widespread adoption; there could be some advantage, he said, in being outside the main stream. As in the NNC report, the seminar summary also reveals clearly the importance attached to the matter of exports in reaching a decision.

Chris Sherwell

BRITAIN

● British industrial journalists were almost buried under an avalanche of figures last week when four nationalised industries published their annual reports. The British Gas Corporation, the Electricity Council, the Central Electricity Generating Board (CEGB) and the Post Office all reported healthy profits. The achievements of the 'energy' industries attracted much attention. In spite of increases in the price of coal and oil and the slow increase in electricity demand, the Electricity Council and the CEGB made profits of £207 million and £130 million respectively. British Gas recorded a £31.5-million profit.

Of major concern to all three is the so-called 'energy gap' expected in the 1990s when North Sea oil and gas become scarce. Each report gives it prominence, and of course it greatly affects both short and long term research programmes. Last year British Gas spent £18.2 million on its R&D programme, the CEGB £11 million and the Electricity Council £41.7 million.

For the CEGB and Electricity Council nuclear power holds the key. But decisions over development to the year 2000 have yet to be taken, so neither has planned a detailed programme. Both, however, are improving existing reactor designs. Research is going on into the possibility of extending the life of Magnox reactors, and the CEGB is pushing ahead for the early operation of advanced gas reactors (AGRs) after the Hinkley Point Station became fully operational earlier this year. Research on the steam generating Heavy Water Reactor (SGHWR) will not increase; but the CEGB has increased its involvement in uranium exploration, and has signed agreements for joint exploration with Conwest Exploration in Canada and Urania Exploration in the USA.

Both the Electricity Council and the CEGB have faced a decline in the growth in energy demand. In view of the uncertainty this brings, the CEGB is giving priority in its more immediate research programme to improving the efficiency and safety of present plant designs rather than developing new plant with an unpredictable future. Taking into account all power stations currently under construction, it foresees no need for further new plants until 1985.

Meanwhile there is little British Gas can do to make gas supplies last into the 1990s except look for new fields and improve efficiency. Last year, as part of its energy conservation programme, it awarded the first Gas Energy Management Award, set up to recognise better use of gas in industry. It is already supporting research to produce natural gas from coal and oil. Last year it successfully manufactured on a commercial scale a new catalyst—CRG-F—for producing substitute natural gas from oil. And at the end of March, a slagging gasifier development programme to make gas from coal, sponsored by an American consortium, came to a successful end.

This latter side of the British Gas research programme overlaps with research done by the National Coal Board (NCB). Sir Derek Ezra, NCB's Chairman, outlined the NCB's £30-million five-year programme for developing new coal technologies when opening an exhibition at the Coal Research Establishment last week. Among its priorities is the manufacture of hydrogen and substitute natural gas from coal.

Perhaps the most surprising figures were those for the Post Office. With a profit of £291.3 million, it had almost doubled the previous year's figure and had succeeded for the first time in ten years in operating its postal service profitably. Of the £51.5 million spent on R&D, the lion's share, £50 million, went on telecommunications. The biggest single project, 'System X', was supported to the tune of £12 million. This is the Post Office's comprehensive telecommunications system of the future, and if it is to be fully developed then the percentage of the Post Office's resources spent on R&D will have to increase.

●After seven weeks of intense examination, British Nuclear Fuels Ltd (BNFL) finished making its case to the Windscale public inquiry last week. Since 14 June fifteen witnesses for BNFL have answered questions on the company's application to extend its reprocessing facilities by building an oxide fuel reprocessing plant. The key issues have been safety, the possibility of plutonium diversion and nuclear proliferation, and BNFL has by and large appeared in a good light. Now it is the turn of the Cumbria County Council and government departments to take the stand.

Just as its case finished, BNFL published its latest annual report. Although it alludes little to the inquiry, the report does mention the effect of the uncertainty surrounding future reprocessing facilities on the renegotiation of some contracts.

In his statement Sir John Hill, the company's chairman, speaks of increasing political constraints on international nuclear trade and economic difficulties in the UK and other trading nations. Still, the figures show BNFL managed to increase its sales of nuclear fuel services to £113 million last year, making a trading profit of £13.5 million, about £1 million up on the previous year. Exports contributed £11.1 million of this, down over £1 million on 1975–76. But there is little worry that the company will not have the money to carry out its investment programme: last year it successfully negotiated a loan agreement for £100 million with a consortium of British and foreign banks.

Ways have to be found of storing fuel as long as possible, especially if it cannot be reprocessed. BNFL is working in close collaboration with other countries on a vitrifying process to solidify liquid fuel for storage in water-filled ponds. The design and construction of a pilot vitrification plant is already under way, but the decision to build a production-scale plant will not be taken before BNFL's work is compared with that overseas. By the end of March, the company had set aside £13 million to pay for the vitrification in the late 1980s of all waste produced since the company was established in 1971.

Another of BNFL's activities which must expand to meet demand is the centrifuge enrichment of uranium. The first centrifuge enrichment plant started operation at Capenhurst last year and has already attracted £1,000 million-worth of business. The company also gained export orders for the conversion of enriched uranium hexafluoride to uranium dioxide using its Integrated Dry Route process.

Judy Redfearn

JET

Delayed again

The Council of Foreign Ministers of the European Economic Community (EEC) met in Brussels last week. Down for decision was the disputed site of the Community's fusion project, the Joint European Torus (JET). Chris Sherwell reports

HEADS of government may make history, but in the EEC they don't appear to determine it. At their meeting in London at the end of June, they insisted that the Council of Foreign Ministers should decide the site for JET at its next meeting. In the event the Council failed to agree. And a research ministers meeting set for two days later was cancelled.

Although the UK Foreign Secretary, Dr David Owen, said last week that he was "very disappointed" by the "non-decision", British newspapers had carried well-briefed reports on the day the meeting started warning that no decision could be expected. This did not apparently contradict earlier reports of a majority in favour of Culham: the majority remained, but only belatedly was it realised that West Germany was sufficiently committed to Garching not to want the embarrassment of an immediate climb-down.

The majority itself was a change from the dark days in March when Culham, or rather Britain, fell from grace. Since then Britain has made some conciliatory gestures, notably in removing her reserve on the EEC's joint research programme, which have helped to restore the site to favour. Britain has also changed tack in her arguments, giving greater emphasis to her concern over the lack of any Community research project in the country (Germany has three) while at the same time acknowledging that Garching is scientifically as suitable a centre to take JET as Culham.

But equally the West Germans have clung tenaciously to Garching. In Britain this is seen in straight political terms: Garching is in what is called 'Strauss country', a reference to the powerful leader of the Bavarian Christian Socialist Union whose influence on potentially shifting political coalitions is so great. An alternative view, that the Germans entertain worries about a Community project going to Britain when the Labour Party is shaping up once more for internal combat over the EEC, is dismissed: it is said that the West Germans know from experience not to doubt the commitment to the EEC of Labour's leaders. Certainly if this was an important factor, it might have been expected to have caused problems across a far broader Community front than just JET.

Not that JET is unimportant. The foreign ministers have now removed the subject almost totally from the hands of the research ministers, whose meeting last week was arranged mainly to clear up loose ends once a decision was taken. But the foreign ministers still only considered the subject informally. Their new president, Henri Simonet, himself a former EEC Energy Commissioner and now Belgium's foreign minister, spoke individually to ministers, taking his own private poll. The subject was then discussed over lunch.

No vote was taken, but it did emerge that if JET was not to go to Culham, it might not go anywhere—a possibility reportedly canvassed by the French, whose own fusion research (notably on Torus II) has been held up by the indecision over JET. Equally, however, if a vote was taken, it would apparently have gone in favour of Culham. One report had it that four countries favoured Culham, two favoured Garching, two were prepared to go with the majority, and one did not pronounce. But that accounting is probably only a 'guesstimate', at best.

Most affected is the JET team itself, based at Culham. Indeed, the lack of a decision is all the more surprising for the fact that the head of the comparable fusion project at Princeton in the United States sent a telegram ahead of the meeting to Paul Rebut, head of the JET team, and Donato Palumbo, director of the EEC fusion programme. The telegram in effect expressed horror at the possibility that JET might not go through and that Europe might not recognise its responsibilities; if JET did not go ahead, it inquired, how many of the team would consider working on the PFTR project at Princeton?

Dr Owen's appeal to the JET team to stay on at Culham, which came after the meeting, was probably made with a eye both to this and to the start of the next school year. Some of the team are thought to have already begun arranging schooling for their children in their own countries, not wishing to wait any longer for a 'final' decision. Their contracts have been extended once again, however, this time to the end of September.

By that time the Foreign ministers ought, with luck and the political will, to have decided on a site. Another meeting is set for 20 September. Between now and then Simonet is expected to visit both London and Bonn to try to iron out the difficulties. His close and long standing relationship with the present Energy and Research Commissioner, Guido Brunner, is expected to help, and though a date has yet to be set, it is on the cards that the British and German heads of government and foreign ministers will meet in Germany for one of their regular bilateral gatherings, the last of which was in London earlier this year.

All will be seeking a way to reach full agreement; a mere majority vote is inadequate under the Community scheme which allows issues not to be decided whenever any single country believes that its national interest is involved. If agreement fails yet again to materialise, JET in its existing form will almost certainly die and Britain and France will probably start initiating their own respective schemes for some other sort of project on a bilateral or trilateral basis. The British prime minister warned of this possibility after the heads of government meeting in June, and there has since been talk in similar terms in both France and Germany.

For the moment the presumption remains that they still wish to cooperate with each other, and to do so through to the Community. It is a presumption increasingly undermined by experience. □

Henri Simonet

EUROPE

Nuclear reports

THE OPPOSITION which the thousands of demonstrators faced at the weekend in expressing their opposition to the Super Phénix fast breeder reactor near Lyons is not confined to the French government alone. The European Commission of the EEC last week voiced its own support for developing fast breeder technology when it released the final two parts of its three-part review on nuclear policy.

Last week's papers were on fast breeders and radioactive waste. A fortnight earlier the Commission released its first paper, on reprocessing. That report, acknowledging the Community's need for nuclear power given its desire to reduce dependence on imported energy, argued that reprocessing would help contain uranium imports and saw greater danger in not reprocessing. The Commission also proposed a special committee to consider a strategy for joint reprocessing.

Last week's breeder report was equally bullish. The limited contribution from new energy sources and the Community's limited access to uranium resources made the breeder an "essential link" in the Community's strategy. Member states had to preserve the option of making the breeder available to utilities on a commercial basis during the early 1990s.

Presenting the paper, Herr Guido Brunner, the Energy and Research Commissioner, insisted that there was no evidence to show that breeders were inherently more dangerous than existing types of reactor, although there were special security problems with plutonium.

- The OECD's Nuclear Energy Agency (NEA), in its annual report published last week, says that even under the most favourable circumstances of high availability and low demand for reprocessing services, the cumulative backlog of unreprocessed material in member countries will increase from 4,000 tonnes U in 1977 to 16,000 tonnes U in 1986, and will remain at that level until 1990. "Uncertainties at the policy-making level" are the main obstacle to adequate reprocessing capacity, it says.

The report also says there is a pressing need to construct large scale demonstration facilities for the solidification and storage of high level waste.

USA

Lost pre-eminence?

The US Office of Technology Assessment has published a report on research in agricultural science. Colin Norman reports from Washington

FOUR major reports in as many years have concluded that basic research in agricultural science in the United States has suffered from financial neglect, and that a modest injection of cash could pay handsome dividends. The latest, a slim volume issued last month by the Office of Technology Assessment (OTA), even goes so far as to suggest that the United States has lost its pre-eminence in basic research to increase food production, because of inflation.

The study, conducted by OTA staff with the help of two outside advisory committees, singles out three areas which should be given particular emphasis—photosynthesis, nitrogen fixation and tissue culture—and it suggests that new funding arrangements should be instituted to ensure that the cash is not siphoned off into other research.

Agricultural research in the United States is mostly funded by the Department of Agriculture, which operates its own research laboratories and channels funds to the State Agricultural Experiment Stations in the form of block grants. No funds are specifically set aside for basic research and, unlike other research agencies in the federal government it does not provide grants for university research on a competitive basis. Virtually every recent study of the agricultural research system in the United States has recommended that the department should institute a competitive grants programme, supporting projects on the basis of peer review; the OTA report is no exception.

One problem with the present system, according to the OTA study, is that since no specific funds are earmarked for basic research, a growing share of the research budget has been taken up by work on immediate problems, such as pest control and disease control, and "the net effect has been to short change basic research whose payoff is long term". Moreover, while basic research has been getting a smaller share of the pie, the pie itself has been shrinking. According to figures compiled by OTA, the Department of Agriculture's total R&D budget this year—$570.6 million —is some $48 million below the 1966 level in terms of purchasing power.

OTA therefore suggests (like all OTA reports, it doesn't actually come out with a hard recommendation) that a competitive grants programme in the Department of Agriculture, specifically designed to boost funding for research on photosynthesis, nitrogen fixation and tissue culture, would pay dividends. Some $15.6 million is now being spent in those three areas by the department, the National Science Foundation, other government agencies and private sources, the report states. It suggests that an additional $12.5 million "appears cost beneficial" in the first year of the new grants programme, and $4–6 million should be added each year for the next six years.

The recommendation is relatively modest. An Academy committee suggested recently that a competitive grants programme should be established with a $60 million initial fund, rising by at least 10% a year in real terms. The programme suggested by the Academy would, however, encompass a vast range of research areas, including studies on nutrition and social policies.

There is at least some indication that repeated calls for such a programme are beginning to be heard in the federal government and in Congress. Earlier this year, President Ford recommended, as part of his valedictory budget, that $27.6 million should be spent on a competitive grants programme in the Department of Agriculture, for a broad range of studies. The funds, in fact, were recommended by the newly-established Office of Science and Technology Policy (OSTP).

A massive agriculture policy bill, now under consideration in Congress, would also elevate research within the department's bureaucratic structure and formally establish a competitive grants programme. The bill has already cleared the Senate, and it was under debate last week in the House.

It is the appropriations committees in Congress which really count, however. Earlier this year, the House appropriations subcommittee which handles the budget for the Department of Agriculture approved only $10 million for competitive grants in the 1978 fiscal year, $17.6 million less than the Administration had recommended. After a bit of lobbying from the White House and from some agricultural scientists, the Senate appropriations committee approved the full $26.7 million, however, and the conference committee which reconciled differences in the House and Senate versions last week came up with a compromise of $15 million. □

USA

- Following the release of a report by the National Academy of Sciences warning of potential long-term climate changes from increased burning of fossil fuels, the Energy Research and Development Administration (ERDA) last week announced the establishment of a new office to plan and conduct a research programme on the problem.

The office will have an initial budget of $1 million, a sum added to ERDA's budget request by President Carter as part of the energy policy he unveiled last April. It will also act as the coordinating unit for other government agencies, and it will keep an eye on international research efforts.

ERDA has also established a panel, under the chairmanship of Dr Alvin Weinberg, of the Institute for Energy Analysis, to assess the potential climatic impact of increased use of fossil fuels, and to recommend a research programme. The panel is expected to produce a report in the next few weeks, and it will form the basis for the new office's research programme.

The Academy committee warned that if use of fossil fuels continues to grow at recent rates, with the industrialised countries switching from oil and gas to coal, carbon dioxide concentration in the atmosphere will probably double over the next century and increase by between 4 and 8 times over the next 200 years. The effect, the committee suggested, may be an increase in average global temperature of about 6 °C toward the end of the twenty-second century.

Though ERDA is taking such predictions seriously, as well it might since the Carter Administration's energy policy calls for sharp increases in the use of coal, ERDA officials are busy noting that there is no immediate crisis and there is ample time to switch to alternative sources of energy if the carbon dioxide problem proves to be serious.

In recent testimony before a Congressional committee, for example, Dr James Liverman, Assistant ERDA Administrator for Environment and Safety, noted that "it is clear that the scientific community cannot today offer the energy strategists a sufficiently confident estimate of the carbon dioxide impact to warrant massive changes in energy forecasting". He added, however, "we must begin discussions with the rest of the world to provide for some flexibility in long-range global energy plans, enough to permit massive reorientation, should it prove necessary, in the next 5 or 10 years".

- Congress last week finally reached agreement on the budgets for the two key basic research agencies in the United States, the National Science Foundation (NSF) and the National Institutes of Health (NIH). Both will get a substantial increase in funds for fiscal year 1978 (which begins on 1 October), though in the case of NSF, the boost will not be as large as the Administration had requested.

In the past few years, NSF's budget request has attracted considerable attention in Congress, as critics of the agency have sought to reduce funds for some of its programmes and to place constraints on its support of school science projects. This year, however, passage was relatively smooth, and NSF officials say they are pleased with the outcome.

NSF will receive $861.3 million next year, a boost of $85.4 million from this year's budget. The Administration had sought $889 million, however, arguing that a major increase is required to offset inflationary losses incurred in support for basic research over the past decade. That argument was challenged strongly by the House Appropriations committee, which stated that "the growth of federal support of academic research has exceeded that of the gross national product by a comfortable margin and has more than compensated for the effects of inflation at a time when other important federal programs were not so favoured". The new budget will, nevertheless, keep NSF a step ahead of inflation.

The only NSF programme to feel Congress's knife strongly this year was the programme of Research Applied to National Needs (RANN), an effort to focus research efforts on pressing national problems. RANN has long been controversial since it puts NSF firmly into the business of supporting applied, rather than basic, research. Congress decreed that RANN should get only $63 million next year, $15 million less than the Administration requested.

As for NIH, a compromise has been reached on the budget bill for the Department of Health, Education and Welfare (HEW), of which NIH is a part, which will significantly increase the Administration's budget request for every institute. The National Cancer Institute (NCI) will again carry off the lion's share of the increases, receiving a budget of $867 million. The National Heart, Lung and Blood Institute comes a distant second with $446 million. The other nine institutes will mostly receive an amount sufficient to account for inflation.

Though the amount budgeted for NIH is unlikely to be changed, the HEW budget bill nevertheless still faces some debate in both the House and Senate on provisions relating to abortion.

- President Carter last week named Arthur C. Upton, Professor of Pathology at the University of New York at Stony Brook, to be the new Director of the National Cancer Institute. The announcement, which had long been anticipated, culminates a long and intensive search for a suitable candidate.

Upton, 54 years old, is an expert on radiation injury and cancer. He recently chaired a committee which recommended termination of a controversial demonstration project, sponsored by NCI and the American Cancer Society, which involved routine breast X-rays for women under the age of 50.

The position of Director of NCI has been vacant since last September, when former Director Frank Rauscher resigned to take a $75,000 per year job with the American Cancer Society. President Ford was reportedly set to nominate pathologist Arnold Brown of the Mayo Clinic for the job late last year, but since he was then a lame-duck president, he decided to leave the appointment to his successor. A search committee was set up earlier this year to look for suitable candidates for the post, and in April it submitted three names —Brown, Upton and Baruj Benacerraf of Harvard.

Colin Norman

CANADA

● Atomic Energy of Canada Limited (AECL) is in trouble again. If last winter was the season of its discontent, it is hard to find a suitable description of its status this summer. Early in July, Energy Minister Alastair Gillespie announced that the Crown corporation had lost about $130 million over a sale of a CANDU reactor to Argentina, and that he had fired the corporation's president, John Foster, as a result. Opposition members called for Gillespie's own resignation because they had warned last winter the loss would be more than $100 mililon, but Gillespie had then maintained it would only be between $23 million and $40 million.

Gillespie rejected their criticism. He did so on the ground that he had invited Ross Campbell to join the board of directors of the corporation, to act as chairman of AECL, and to renegotiate the AECL contract with Argentina. Campbell was a former ambassador to Japan. Gillespie told the House of Commons earlier this year that the renegotiation would reduce the losses, estimated by an auditor-general's report to amount to $100 million because of inflation, by about $60 million to $80 million. The renegotiation was to be made on the basis of the sale of a second reactor.

But Campbell's appointment as acting president of AECL temporarily to replace John Foster brought more criticism. The New Democratic Party's energy critic, T. C. Douglas, asked incredulously in the House: "Do I understand the minister is telling me that prior to the signing of a renegotiated agreement he was given the information that the loss would be cut to somewhere between $23 million and $40 million, that he now finds that those who drafted the agreement and signed it have incurred a loss of $130 million, and that the man who carried on the negotiations now is being appointed president of AECL?"

Gillespie should resign, said Douglas. So did Allan Lawrence, of the Progressive Conservative Party. But Gillespie defended the earlier figures on the loss, saying it was the best information the company had at the time. He defended Campbell by saying that a team of negotiators was involved in the Argentina talks, and that Foster, not Campbell, was then the corporation's chief executive officer.

The government has repeatedly found itself in difficulty over the Argentina sale. At first it was opposed on the ground that it could lead to nuclear weapons proliferation, because Argentina was regarded as unstable politically. Then the House of Commons' Public Accounts Committee questioned a $2.4 million commission paid by Canada for AECL's sale of the reactor to Argentina. The commission was paid into a Swiss bank account held by a trading firm in Leichtenstein, but AECL did not know the name of the agent or whether it was the Liechtenstein firm.

● Another summer landmark has been the passing by the House of Commons of the bill re-organising the federal fund-granting agencies for university research, Bill C–26. Changes in the granting councils were recommended years ago by the Lamontagne committee, the Senate special committee on science policy. The government promised them as long ago as 1974.

Under the new legislation two new fund-granting councils will be created —the Natural Sciences and Engineering Research Council and the Social Science and Humanities Research Council. The former will take over the granting function of the National Research Council, leaving it free to concentrate on its other functions. The latter will take over responsibility for awards in the social sciences and humanities, and the Canada Council, which formerly handled such grants, will deal solely with the arts.

A new Inter-Council Coordinating Committee will maintain liaison and communications between the three award-granting bodies (the third being the Medical Research Council, whose function remains largely unchanged). The new committee, made up of the three council presidents, will be chaired by the secretary of the Ministry of State for Science and Technology.

In discussion in the House, the Minister of State for Science and Technology, Mr Hugh Faulkner, said he believed the re-organisation of the granting councils "will open the way to a new relationship between the government and universities in research matters". He noted that, in the past, there has been "little, if any, coordination of university research objectives regionally or nationally."

Curiosity-oriented research must continue to receive support, said Mr Faulkner, but a more selective process is needed to allow the relatively few individuals whose research is of recognised quality to be supported well—perhaps better than in the past.

The *laissez faire* attitude to the support of university research had a much narrower validity than it once had. This meant the time had come for a "more activist" approach by the granting councils.

● The chairman of the Science Council of Canada, Josef Kates, used the publication of the council's eleventh annual report as an occasion to punch home a theme that has become perhaps the organisation's most important: technological sovereignty.

In his annual statement in the report, Dr Kates said that if Canada was to create long-term stability and respond to the dictates of Canadian geography in an increasingly interdependent world, it must stimulate and control the development of technologies essential to the well-being of the nation. "In this last quarter of the twentieth century, Canada will need to assert *technological sovereignty, that is, to develop and control the technological capability to support national sovereignty,*" he said (his emphasis).

Because of historical factors and recent policies, Canada found itself in a weak position industrially, Dr Kates said. Industries that had been the leading edges of the industrialised economies for the last twenty years were the weakest in Canada. To attain technological sovereignty, Canadians would have to control technologies considered vital to Canada; develop indigenous technological capabilities in selected areas (with government adopting a "buy Canada" policy); encourage internationally-competitive high technology firms in specific areas and develop small, innovative technical firms; and set up major government-sponsored programmes to meet national needs.

At a press conference releasing the report, John Shepherd, executive director of the council, said the first step required in getting major programmes into operation (long a council objective), was to get Cabinet agreement. He referred to the history of oceans systems as a classic example of what happens to major programmes in Canada: Council identified ocean systems as a priority area in 1971, and Madame Jeanne Sauvé, then Minister of State for Science and Technology, approved the idea in a policy statement in 1973. But to date, the government has set no priorities for the programme.

David Spurgeon

IN BRIEF

Séveso row

When the release of dioxin at Séveso last year was considered at an ecotoxicology workshop held this week under the auspices of NATO's Ecosciences panel, the means of assessing the extent of dioxin poisoning in humans generated heated debate. Dr Guiseppi Reggiani, director of medical research for Hoffmann-La Roche, claimed that chloracne, the disfiguring skin disease observed in some 100 Séveso schoolchildren, was an "obligate sign of dioxin contamination".

Professor Silvio Garattini and Dr Gianni Tognoni of the Mario Negri Institute, Milan, the two main Italian participants, delivered scathing replies. Garattini described Reggiani's statement as "dangerous", and insisted that there was "no acceptable scientific evidence" to support it. He couldn't accept the implication that the surveillance programme of all residents, and not just children, was a waste of time. Reggiani adhered to his view, and for the future forecast that there would be "no severe health damage to the population at Séveso". The Italians remained unconvinced.

Lead in water: report

The UK Department of the Environment last week published detailed results of a survey carried out in 1975 on levels of lead in Britain's drinking water. The main findings showed that approximately 4% of houses in Britain received water containing more than 0.1 mg of lead per litre during the daytime. About 9% exceeded this level first thing in the morning after water had been standing in pipes during the night. Less than 1% regularly exceeded 0.3 mg per litre.

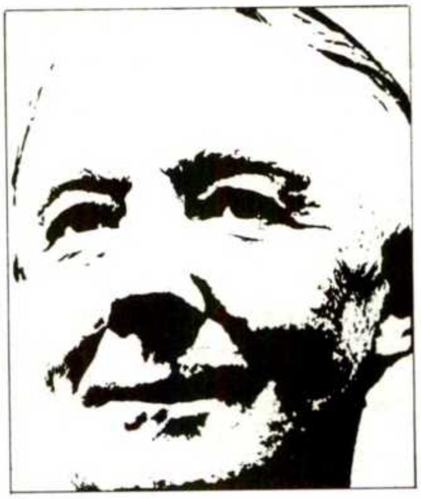
The survey found that water fed into the public supply in Britain contains minimal levels of lead; but in some areas it has a tendency to dissolve lead in pipes. In a statement, the minister, Mr Peter Shore, said there was a need for more research into the precise causes of lead in water, possible ways of minimising it and the effect it has on health.

The World Health Organisation's upper limit for lead concentrations in water is 0.3 mg per litre.

Oil spill policy

The government set out its policy for coping with oil spills at sea last week. Wherever possible, it states, oil spills should be left to degrade naturally; but where there is a serious pollution threat chemical oil dispersants should be used. Provision will be made to cope with spills of 16,000 tonnes per day offshore and 1,000 tonnes per day onshore and in inshore waters.

People projections



KENNETH MELLANBY

For the last ten years we have been bombarded with propaganda about impending world overpopulation. Even in countries like Britain, where the increase is relatively slow, it has been pointed out that if this continues we too will have 'standing room only' within a few hundred years. Though this will not happen, things could become more uncomfortable. But planning even for shorter periods such as the next twenty or thirty years could be much more effective if we had reasonably accurate population forecasts. Our Office of Population Censuses and Surveys (OPSC) makes a valiant effort, but their results have, so far, not been very encouraging.

During the first twenty years after the 1939–45 War, the birth rate was unexpectedly high, particularly among the middle classes, when Britain's 'top people' proudly announced in the *Times* newspaper that they had produced "Jemima, a sister for Jason, Emma, Susan, Giles, Jeremy and Natasha". The country had a minor population explosion. Then during the last ten years the forecasts have been bedevilled by the unexpected and catastrophic drop in the birthrate, so that Britain's population is actually falling.

The effects of this recent change are well illustrated in the recent OPCS Monitor giving population projections for England and Wales up to the year 2010. In 1970 there were about 800,000 live births; the estimate for the total population for 2010 was 62 million. By 1976 births had fallen by some 200,000, and based on this figure the forecast for 2010 was only 51 million. It will thus be seen that, using the methods now available, very small changes in the birthrate have substantial effects on further population projections. Every baby not born this year will subtract something like 50 individuals from the figure for 2010.

In less developed countries, population increase results mainly from the falling death rate. This is less important in Britain, where people mostly live longer, but the OPCS suggest that over the next 40 years there may be a further fall of 10% in the death rate, mainly affecting the young (infant and neonatal mortality) and the aged. This would produce a larger number of men and women over 70, and impose an increasing burden on health services and pension funds. But will this forecast be any more accurate than that about births? We know that rats underfed in the their youth live much longer than their littermates who receive a generous diet. Are overfed babies, toddlers, teenagers and adults likely to survive as well as previous, more austerely raised, generations?

When Britain's population was growing rapidly, in the late 1960s and early 1970s, there were many calls to our various governments to implement population policies to produce, as soon as possible, stability ('zero population growth'). Both Labour and Conservative governments made sympathetic noises, they set up commissions and committees, and they did absolutely nothing.

Britain's politicians must now be kicking themselves for not being able to take the credit for the greatly reduced birthrate. If only in 1969 or 1972 they had promulgated a definite policy—any sort of policy—and had appeared to act vigorously, they could now point out that although they had not stimulated economic growth, built more houses or cured unemployment, their population policy had been completely successful. However, the cynic may say that, had government encouraged population stability, we would all have responded by breeding like rabbits.

Translating Chinese texts

SIR,—Whilst preparing a written translation of taxonomic material from Chinese into English some time ago, I was struck by the great disparity between the highly specialised vocabulary of the subject and the simple nature of the grammar employed. This led me to wonder whether Chinese character data-handling techniques, with which I was then involved, might be applied to taxonomic texts to transform them relatively directly by machine into pidgin-English, adequate to convey the original data to the English-speaking reader, working in the appropriate scientific field. This approach seemed viable because Chinese in its written form is morphemic, each character conveying a quantum of meaning, and pidgin, which is itself primarily a direct transformation of Chinese sentences into English on a word-for-word basis, is a basic means of communication over parts of the Pacific Ocean.

An early stage of experiment, using a flowchart which was followed manually, showed that the original idea was promising, but the time-consuming nature of the work meant that relatively little material was processed. Later experiment, however, has involved actual machine processing of a number of texts, and the original ideas have been refined to accommodate some idiosyncrasies of Chinese word order, and to allow smoothing of the finished product. However, these improvements have been achieved without the need to use manual pre- or post-editing, the aim always having been to produce intelligible output by a routine operation which can be run by an operator whose only skill need be the identification of the Chinese characters in the original text.

The process which has been developed is not a linguistically-based general translation programme. It relies for its effectiveness on the careful selection of multi-purpose glosses to represent multi-functional Chinese units in such a way that the reader's general knowledge of the field forces him into the correct choice of gloss for the context facing him. It is only in restricted areas, such as that found in taxonomic texts, that successful transformation can operate, and then it will only produce pidgin, however smoothed, rather than everyday English. However, I feel that the results so far indicate probable eventual success in providing a workable first sieve for the assessment of the large bulk of Chinese taxonomic data which at present seems to be largely unavailable to the Western scientist.

In spite of its inherent interest, it would be of little practical use to develop pidgin transformation further in the absence of any live demand for such a facility. If any readers feel that this type of transformation of taxonomic material would be of benefit to them, I would be grateful to hear from them. To give some idea of the form of output from the process, I append the result of one machine transformation, which shows the general style, and also illustrates how the multi-choice glosses operate (see below).

Wind power for the UK

SIR,—Some comments are necessary on Martin Ryle's article on 'Economics of alternative energy sources', (12 May, page 111). Whilst his suggestions on storage systems may be useful, his claim that wind power could be a substantial energy resource without much environmental impact is grossly exaggerated.

The coastal area of the UK is not 1.5×10^4 km^2 as stated in the article; in fact the total land area of the UK[1] is only 2.4×10^5 km^2. To obtain an annual output of 0.56×10^9 GJ at a mean density of 2.8 GJ m^{-2} from a swept area that is 4×10^{-3} of the ground area (all figures quoted), one would need an area of 5×10^4 km^2. Thus a fifth of the total area of the UK would have to be covered with towers about 60 m in height at distances apart of about 1 km. It is questionable whether this is practicable. The costs of siting the aerogenerators over all types of country have not been estimated.

In any case the visual impact on the environment would be overwhelming, and in our windier more scenic areas the view would mainly consist of endless rows of towers stretching in every direction. Also the question of noise from the 1 MW turbines, which will be only 1 km apart, is not mentioned.

A more practical upper limit on energy from wind power has been estimated by the Energy Technology Support Unit at Harwell to be the equivalent of about 8 million tons of coal a year from 10^4 generators each of about 1 MW rating[2]. Without an immense cost to the environment wind power could not make a substantial contribubtion to Britain's energy requirement.

Experimenting with controlled gravity

from P. C. W. Davies

Our everyday experience of gravity is so pronounced that it is easy to forget what an incredibly weak force it really is. Only our proximity to a mass as large as the Earth enables terrestrial gravitational forces to compete with other forces of nature. By contrast, in the laboratory, gravity is almost completely undetectable: the force of attraction between two eggs in contact is a puny 10^{-6} dyne. This state of affairs has led to an extreme paucity of actual experiments in gravitational physics, because most of them have to rely on the arrangement of astronomical masses in the Solar System to produce effects which are sufficiently strong to be detectable. Unfortunately, the limited repertoire of planetary activity prevents some features of gravity from being measured at all. There have been two major theories of gravity: Newton's and Einstein's. Both have relied heavily on astronomical effects in the Solar System for their verification.

Because gravity is so ill-investigated, almost any proposal for a new experiment is welcome. In a paper in this month's *Physical Review*, three physicists, V. B. Braginsky of the Moscow State University, C. M. Caves and K. S. Thorne of Caltech (*Phys. Rev. D*. **15**, 2047; 1977), propose a collection of novel experimental techniques for measuring gravitational effects, some of which have never been observed but are predicted by theory. The essence of the new proposals is that rapid advances in technology are opening up the prospect of detecting in the laboratory sources of gravity which are under the control of the experimenter. None of the experiments discussed is currently feasible, but several could become so within a decade with sufficient research and development. Some of the technology gained could even have useful spin-off in other fields.

Laboratory-generated gravitational forces are so tiny that equipment of immense sensitivity is needed to detect it. Three new low-dissipation sensing systems are considered by the authors: a torque balance made of quartz or sapphire fibres cooled to 0.1 K, massive dielectric monocrystals cooled to millidegrees, and microwave resonators with superconducting walls. Typically, the source of the fields would be a mass of about 100 kg rotating about 1,000 times a second, which would be capable of producing accelerations due to higher order (post-Newtonian) effects in its vicinity of about 10^{-17} cm s^{-2} (or 10^{-20} g). The major technological problem is how to isolate this effect of interest from other environmental disturbances, particularly seismic effects, which are many orders of magnitude larger. One answer is to conduct the experiments in Earth-orbiting satellites; less expensively, some of them could be performed in tandem and the seismic perturbations subtracted, or they could utilise high frequency time-dependent fields, far above natural seismic frequencies.

Some of the experiments are reminiscent of nineteenth century electrodynamics. One involves the analogue of Ampère's experiment, which demonstrated magnetic forces between current-carrying wires, only in this case the role of the electric current is taken by rotating masses one of which is part of a torsion balance. The rotation period of the other mass is modulated at the natural frequency of the balance in an attempt to set up torsional deflections. A corotating arrangement causes repulsion, and counter-rotation attraction. This 'magnetic' gravity force is expected on theoretical grounds, but has never been observed. Even in ideal laboratory conditions, using light but tough ceramic masses, the problems of untangling the minute 'magnetic' effects from the already tiny, but much larger Newtonian gravitational attraction, not to mention the disturbances from seismic vibrations, are daunting. Nevertheless, the authors do not think it beyond the ingenuity and technological expertise of the next 'generation' of experimenters.

Other possible experiments using the torque-balance are a check on any time-dependence in the strength of gravity (which is predicted by some theories) and a measurement of the gravity produced by magnetic stresses. In the former set-up the entire apparatus, consisting of two massive balls straddling the balance, is made out of monocrystal sapphire cooled to 2 K and kept in a constant temperature environment to eliminate thermal fluctuation noise. After one month, a limit on variation of the Newtonian constant G of about one part in 10^{11} yr^{-1} could be achieved, which is already comparable to astronomical techniques. Turning to the latter experiment, it is particularly important for theory, because general relativity predicts that not only mass, but stress, contributes to gravity. Indeed, in some astrophysical situations, stress-induced gravitational fields can be extremely important, so a direct measurement of the gravity of stress would be of great significance.

In another class of experiment the authors discuss the use of a toroidal cavity filled with a standing-wave pattern of electromagnetic radiation. If this resonator is placed at rest round a rotating mass, according to the theory of relativity the wave pattern should be dragged around in the direction of rotation, an effect known as the dragging of inertial frames. For a mass of 5,000 kg rotating with an equatorial speed of 1 km s^{-1}, the dragging effect works out at a mere 6×10^{-21} radian s^{-1}, which is small by any account. Nevertheless if future technology enables the construction of a resonator having superconducting reflecting walls with a damping time (against decay of the wave pattern) of 10^5 s—which is difficult but not outrageous—then deflections in the wave pattern of 3×10^{-16} radians are feasible, which might be detectable over a duration of about 2 weeks. An improvement in the

---

P. C. W. Davies is a lecturer in Mathematics at King's College, London.

reflection coefficient R of the cavity walls, from the presently attainable $1-10^{-11}$, to $1-10^{-14}$ would be necessary to sustain an experiment of this duration.

The third class of experiment utilises massive dielectric monocrystals in which the experimental arrangement is such as to eliminate the ordinary Newtonian force, which usually dominates all else, and to detect just the post-Newtonian subtle correction effects of interest. One of these experiments is the analogue of the Faraday effect in electrodynamics, in which a changing magnetic field threading a detector coil induces an electromotive force (the principle of the transformer). In the gravitational variant, the 'magnetic' induction is produced by a uniformly rotating vertical cylinder set coaxially with an axisymmetric, specially shaped, sapphire crystal, which is free to perform torsional oscillations. As the cylinder is moved up and down at the natural frequency of these oscillations, changing 'gravimagnetic' flux linking the two masses drives the torsional oscillations The force involved is incredibly small—producing accelerations of only 10^{-18} cm s^{-2}. In this regime even the act of measurement of the oscillations could introduce Newtonian gravitational forces between the masses which are of comparable strength.

Less feasible experiments are also discussed in which gravitational fields are detected which originate, at one extreme with the uneven distribution of matter in the Galaxy, and at the other with a beam of relativistic protons from a storage ring. In the latter experiment, a pulse of high velocity protons passes close to a monocrystal detector at periodic intervals in an attempt to set up resonant oscillations through gravitational coupling. If successful, the experiment would discriminate between scalar, vector and tensor gravitational fields, and is hence of considerable theoretical interest. Technological problems abound though, and little investigation of disturbing effects, such as bombardment of the detector by radiation from the storage ring, has yet been conducted.

All in all, this analysis provides a speculative but thought-provoking basis for more detailed feasibility studies. Much of the current impetus in experimental gravity research is behind astronomical and spaceflight technology. With the colossal cost involved in conducting extraterrestrial experiments, perhaps the time has come for a more penetrating appraisal of the possibilities for detecting and measuring laboratory-manipulated gravity. ☐

Reading the tumour virus genome

from B. W. J. Mahy

THE strategem by which an RNA virus directs the host cell to synthesise virus-specific protein components continues to fascinate biochemists. Broadly, the RNA viruses are comprised of two groups, those in which the genome RNA acts as messenger for protein synthesis (positive-strand viruses) and those in which the genome RNA is of the opposite sense to messenger, and must be transcribed into a complementary RNA species (cRNA) to initiate multiplication (negative-strand viruses). The RNA tumour viruses (oncornaviruses) along with picornaviruses (such as polio), togaviruses (such as Sindbis) and most plant viruses, fall into the first group. Thus genome RNA extracted from these viruses is an active messenger in cell-free protein synthesising systems and, in the case of picornaviruses, RNA of genome size is found on polysomes of infected cells where it translates into a full-length polyprotein that is subsequently cleaved into the capsid and other virus-specific proteins.

But in many other cases the situation is not so simple. The 42S genome RNA of togaviruses is infectious and can direct the synthesis of some polypeptides in a cell-free system but these are not the virus structural polypeptides. A subgenomic species of RNA (26S) found on infected cell polysomes is the messenger for the synthesis of a polyprotein which undergoes post-translational cleavage to form the virus structural proteins (Cancedda *et al. J. Virol.* **14**, 652; 1974; Clegg & Kennedy *FEBS Lett.* **42**, 327; 1974; Simmons & Strauss *J. molec. Biol.* **86**, 397; 1974; Wengler *et al. Virology* **61**, 120; 1974). This 26S RNA represents one-third of the genome and is located inward from the 3′ end of the 42S RNA (Kennedy *J. molec. Biol.* **108**, 491; 1976). Translation of the 42S RNA itself is initiated at a single site near the 5′ end (Cancedda *et al. Cell* **6**, 215; 1975) but terminates before the structural protein genes; the product is a polyprotein which is cleaved to form various non-structural polypeptides, probably including components of the viral replicase (Brzeski & Kennedy *J. Virol,* **23**, 420; 1977). It seems that a similar type of translational control is employed during the replication of some plant viruses. Tobacco mosaic virus RNA, for example, directs the synthesis *in vitro* of two non-structural polypeptides which are components of the viral replicase, but the coat protein gene located near the 3′ end is not translated. The functional mRNA for coat protein is a subgenomic species found in infected cells (Hunter *et al. Nature* **260**, 759; 1976).

Currently, interest in the translation of the RNA tumour virus genome is at fever pitch. These viruses replicate by transcription of a DNA provirus integrated into the host cell genome, and virus-specific polysomal RNA is of the same sense as the genome RNA. The reason for the current excitement is the clear demonstration from several groups that the genome RNA of viruses which induce sarcomagenic cell transformation (non-defective viruses) contain a distinct gene (*src*) located near the 3′ end (Joho *et al. Proc. natn. Acad. Sci. U.S.A.* **72**, 4772; 1975; Wang *et al. J. Virol.* **16**, 1051; 1975; Stehelin *et al. J. molec. Biol.* **101**, 349; 1976). Identification of the *src* gene product is crucial to our understanding of the mechanism of cell transformation. Since transformation-defective viruses lack this gene, comparison of the *in vitro* translation products of their RNA with non-defective virus RNA should yield information on the nature of the *src* polypeptide.

The genome of RNA tumour viruses consists of two identical 35S subunits each of molecular weight $3{\cdot}3\times10^6$ and containing genes for internal structural proteins (gs antigens, *gag* gene) envelope glycoproteins (*env* gene) and the virus RNA-dependent DNA polymerase (*pol* gene) in addition to *src*. The genes of avian oncornaviruses have been mapped in the order 5′-*gag*-*pol*-*env*-*src*-3′ (Wang *et al. Proc. natn. Acad. Sci. U.S.A.*, **73**, 1073, 1976), and it is highly probable that the same gene order occurs in the murine oncornavirus genome.

Recently Alan Smith's group at Imperial Cancer Research Fund translated the genome RNA of Rous sarcoma virus in a variety of cell-free protein-synthesising systems (Pawson *et al. J. Virol.* **19**, 950; 1976). In each case the product turned out to be a polypeptide of molecular weight 76,000 which was related to the internal structural proteins (*gag* gene) as judged by immunoprecipitation and peptide mapping. The other virus gene products

---

Brian Mahy is Assistant Director of Research in Virology in the Department of Pathology, University of Cambridge.

were not detected, and no differences were observed between non-defective and transformation-defective virus RNA. Duesberg's group obtained similar results (von der Helm & Duesberg *Proc. natn. Acad, Sci U.S.A.* **72,** 614; 1975).

An important finding by Pawson *et al.* was that the 76,000 molecular weight product could be labelled *in vitro* with chemically formylated ^{35}S-Met-tRNA$_f^{Met}$, which only labels at the N-terminal position. This confirmed that the 76,000 polypeptide was a primary translation product and not derived from cleavage of a larger molecule.

In this issue of *Nature* (page 416) Pawson *et al.* have extended their work by examining the translation products of RNA obtained from Rous sarcoma virus-infected cells. Two size classes of virus-specific RNA, one around 3×10^6 daltons (35S) as in the viron, the other around 1.3×10^6 daltons (24S), are found in the cytoplasm of cells infected with avian sarcoma virus (Bishop *et al.* in *Animal Virology,* ed. Baltimore D. & Huang A. S., Academic Press, 1976). Pawson *et al.* find that the intracellular 35S RNA when added to cell-free protein-synthesising systems codes for only one polypeptide of molecular weight 76,000 which corresponds exactly to the *gag* gene product synthesised from virion RNA. However when they add to the system 20–25S RNA from infected cells, a new polypeptide of molecular weight 70,000 is synthesised, and this is immunoprecipitated only by antiserum against the virus glycoproteins. It seems therefore that the 20–25S from infected cells encodes the *env* gene and is a subgenomic species similar to the 26S RNA of togaviruses.

Results in agreement with these have been obtained by Hanafusa's group at the Rockefeller University, who microinjected either 35S or 21S RNA from avian leukosis virus-infected cells into chick embryo fibroblast cells infected with the Bryan high-titre strain of Rous sarcoma virus, which lacks the ability to synthesise its own envelope glycoproteins. Production of infectious Rous sarcoma virus provided a sensitive assay for envelope mRNA and it was found that 21S RNA but not 35S RNA expressed this activity (Stacey *et al. Proc. natn. Acad. Sci. U.S.A.* **74,** 1614; 1977).

Recently, very similar findings have been made with the murine RNA tumour viruses. Both 35S and subgenomic (20–25S) RNA species are found in cells infected with these viruses (Fan & Baltimore *J. molec. Biol.* **80,** 93; 1973; Gielkens *et al. Proc. natn. Acad. Sci. U.S.A.* **71,** 1093; 1974), but the 35S RNA species alone is found on polysomes immunoprecipitated with antiserum to virus internal structural protein (Mueller-Lantzsch & Fan *Cell* **9,** 579; 1976). Direct translation of the two intracellular RNA species has recently been achieved by injection into *Xenopus* oocytes (Van Zaane *et al. Proc. natn. Acad. Sci. U.S.A.* **74,** 1855; 1977). The products, identified by immunoprecipitation, were shown to be internal structural proteins (*gag* gene) for the 35S RNA and envelope polypeptides (*env* gene) for the 22S RNA.

From these results it seems clear that the only 'open' cistron available for translation from the 35S genome RNA of oncornavirus is the *gag* gene, located nearest to the 5′ end. Presumably the internal initiation sites for the other gene products are blocked in an analogous manner to the structural protein genes of togaviruses. Several problems remain. The *env* mRNA can be identified as a discrete species in infected cells, but the mechanism of its synthesis by post-transcriptional processing or by some other means is not known. It may be relevant that subgenomic negative-strand RNA species which could be templates for mRNA synthesis have recently been identified in cells infected with RNA tumour viruses (Stavnezer *et al. J. Virol.* **20,** 342; 1976).

The mRNAs coding for the *pol* gene product or the *src* gene product have not been identified as yet. However, if the model proposed by Pawson *et al.* is correct, one possible way to get at the *src* gene product might be to use suppressor tRNAs to allow readthrough of all the genes in 35S RNA from transformation-defective and non-defective viruses. □

Amorphous semiconductors

from A. R. Long

The 7th International Conference on Amorphous and Liquid Semiconductors was held at Edinburgh on 27 June–1 July, 1977.

In the past, the study of amorphous semiconductors has been only loosely related to the wider field of study embracing the analogous crystalline materials. It has rather been dominated by ideas of electron localisation peculiar to disordered lattices. However, recent developments reported at the conference imply a significant change of emphasis, with a much stronger concentration on the non-crystalline analogues of well-known phenomena of the ordered state. This development was stimulated by the now well-documented discovery of the technique for doping amorphous silicon films prepared by the glow discharge decomposition of silane, to produce the familiar n-type and p-type materials and p-n junctions.

W. E Spear and his coworkers (University of Dundee) presented a number of papers giving a coherent account of the electronic properties of doped amorphous silicon prepared by their glow discharge technique. Other groups, notably from IBM, Xerox, Harvard and the University of Chicago, working with similar material, emphasised the importance of hydrogen incorporation in these films in reducing the density of defect related electron states within the energy gap and thus enabling doping to take place However, it is not possible to say at present if the substantial proportions of hydrogen contained in these films are themselves influencing the band structure of the material nor whether the doping process *per se* disorders the network further, thereby changing the intrinsic properties of the material as well as moving the fermi level. Much work remains to be done on these materials, particularly as they are of potential commercial importance.

The anomalous sign of the Hall effect observed for some amorphous semiconductors has long been a puzzle. D. Emin (Sandia Laboratories) described the manner in which the sign of the Hall coefficient is influenced by the connectivity of the appropriate structural units in the network and also the progress made in accounting for the magnitude and temperature dependence of the Hall mobility With this work, an important technique in developing our understanding of crystalline semiconductors can now be applied with more confidence to the amorphous state.

The most striking recent theoretical advance in the physics of disordered materials has been the realisation, initially by Street and Mott, that the nature of electronic defect states may be profoundly influenced by the local atomic configuration, and in particular that pairs of singly occupied dangling bond states may in certain circumstances be energetically unstable and tend to form their charged analogues.

A. R. Long is in the Department of Natural Philosophy at the University of Glasgow.

These ideas may be used, as was reported in a number of papers, to explain a wide variety of low temperature photo-induced properties of chalcogenide glasses. Moreover, when interpreted within the chemical framework appropriate for chalcogenides, the 'valence alternation pair' model of Kastner, Adler and Fritzsche, they provide a convincing explanation of why it is not possible to move the fermi level in chalcogenides by doping in the traditional manner. Investigations were reported, by a group from Energy Conversion Devices led by S. R. Ovshinsky, of the modification of chalcogenide transport properties by the introduction of considerable atomic fractions of charged impurities into the matrix. However, the exact nature of the changes occurring in this modification process and the influence of the preparation conditions used are unclear at present, and it remains to be seen whether such modified chalcogenides will be of any lasting importance.

One interesting feature of the conference was the dominating position of certain lines of investigation and the virtual eclipse of topics which have dominated previous meetings. Little new structural work was reported, possibly because of the difficulty in interpreting unambiguously the results from traditional structural probes. However, the relatively new study of X-ray absorption fine structure (EXAFS), reviewed for the conference by D. E. Sayers (North Carolina State University) is an important advance, in that individual atomic species in multicomponent systems can be studied separately, and new results using this method were reported, particularly striking being the investigation of the coordination of arsenic impurities in amorphous silicon by the Xerox group. Recent studies of liquid semiconductors were restricted to two sessions, concentrating on conduction mechanisms. The thermal and vibrational properties of the disordered state which show highly anomalous features, were comparatively neglected, though important new results interpreting the dielectric properties of low temperature glasses in terms of polar two-level atomic states were presented by the Stuttgart/Grenoble group.

Papers concerned with applications of amorphous semiconductors were also few. David Adler (Massachusetts Institute of Technology), in a subtle and convincing analysis of a particular class of chalcogenide threshold switching devices, was able to demonstrate that thermal effects are insignificant and that electronic mechanisms are responsible for initiating and sustaining the on-state. Although there is undoubted interest in the fabrication of thin film photovoltaic cells for energy conversion, little progress was reported beyond a definition of the design criteria, which will have to be met. It will be interesting to see if our enhanced understanding of basic processes can be turned into marketable devices by the time of the next international conference in this series.

From the papers presented at this conference, it is apparent that the study of amorphous semiconductors has progressed beyond the stage where uncertainties in the preparation conditions had a profound influence on observations. If an amorphous material is carefully prepared under well controlled conditions, and suitably characterised, it will in general be possible to make consistent measurements of its physical properties, which was by no means true in the early years of the subject. However, our theoretical understanding of many of the processes taking place in these materials is still weak, and the identification of the specific structural features responsible for particular effects almost nonexistent. It is to be hoped that, with more reliable experimental data becoming available all the time, these deficiencies will soon be rectified. □

Calcium and muscle regulation

from S. J. Smith

MUSCLE contraction involves the repetitive interaction of crossbridges from thick filaments with thin filaments, impelled by the hydrolysis of ATP. Although calcium is the universal intracellular signal which triggers contraction, there seem to be two targets for its action. In vertebrate skeletal and cardiac muscle, a subunit of the troponin complex on the thin filament is the calcium receptor; in the absence of calcium this complex impedes the interaction between actin and myosin. According to the currently favoured 'steric blocking' theory, calcium binding is accompanied by a movement of tropomyosin, a rod-like protein, which lies in the two grooves formed by the double helical array of actin monomers; the myosin-binding sites on actin are thereby exposed, allowing contraction to occur. In contrast, in invertebrates, regulation has been found to be linked to the myosin molecule, involving specific regulatory light chains. The most extensively studied system is that of the scallop, where the selective release of one of the two chemically identical regulatory light chains by EDTA results in the abolition of calcium sensitivity of the actin–myosin interaction (Kendrick Jones *et al.* *J. molec. Biol.* **54,** 313; 1970). This is accompanied by the loss of half of the calcium-binding sites on the parent myosin. Calcium regulation is completely restored by replacement of the absent light chain in the presence of magnesium. This suggests that both light chains are necessary for regulation, and work by Szent-Györgyi *et al.* (*J. molec. Biol.* **74,** 179; 1973) implies that both myosin heads are cooperatively involved.

The advantages of the different types of regulation are not yet understood, and do not seem to be correlated with the speed of contraction of the muscle (see discussion by Lehman *Int. Rev. Cytol.* **44,** 55; 1976). In some phyla both regulatory mechanisms exist. The approach of Harris and Epstein (*Biochemistry* **16,** 859; 1977), who are investigating the contractile proteins of mutants of a 'dual-regulated' nematode worm, may prove valuable if mutants defective in one or other of the regulatory systems can be isolated.

There is no simple phylogenetic pattern for distribution of the regulatory systems. Myosin-linked regulation is not confined to invertebrates, but has been demonstrated in the smooth muscle of higher vertebrates (Bremel *Nature* **252,** 405; 1974). Recently, the mechanism of this regulation has been extensively investigated in chicken gizzard and pig stomach muscles (Sobieszek *Eur. J. Biochem.* **73,** 477; 1977; Small & Sobieszek *Eur. J. Biochem.* **76,** 521; 1977). It seems that the triggering of the actin–myosin interaction is brought about by calcium-dependent phosphorylation of the 20,000 dalton light chain by a specific light chain kinase. This occurs very rapidly and *in vitro* can be shown to precede the rise in actin-activated ATPase activity, suggesting that the process is physiologically important. Dephosphorylation occurs through the action of a phosphatase, which is not calcium sensitive and is present in approximately equivalent amounts to the kinase. The site of action of calcium is not yet certain; although smooth muscle myosin itself binds calcium in significant amounts, the isolated 20,000 dalton light chain does not, although it can be phosphorylated in the presence of calcium. This would suggest that calcium acts solely in the phosphorylation process but could also be consistent with a scheme whereby some interaction with the heavy chain is necessary for calcium binding by the light chain. The part that tropomyosin could play in a myosin-linked regulatory system was unclear. However, recently Sobieszek

S. J. Smith is in the Department of Biophysics at King's College, London.

& Small (*J. molec. Biol*, **112**, 577; 1977) have shown that tropomyosin is necessary for amplification of the affect of phosphorylation, being required for the full development of actin-activated ATPase activity. It would seem that, on calcium activation, as in skeletal muscle (reviewed by Weber & Murray *Physiol. Rev.* **53**, 612; 1973), tropomyosin brings about a cooperative change in the actin filament, which facilitates the actin–myosin interaction.

Whereas myosin-linked regulation in smooth muscle now seems to be indisputable, it is not certain whether troponin is present in these muscles. Ebashi reports (Mikawa *et al. J. Biochem.* **81**, 273; 1977) an 80,000 molecular weight calcium-sensitising factor, which has no kinase activity. Moreover troponin C, the calcium-binding component of the complex, has been isolated from uterus muscle by affinity chromatography using troponin 1, the inhibitory unit of the skeletal muscle complex (Head *et al. Biochem. J.* **161**, 465; 1977). However, *in vitro* functional tests suggest that there is no thin filament regulation (Sobieszek & Small *J. molec. Biol.* **102**, 75; 1976). It seems possible that this calcium-sensitising factor performs some other, as yet unrecognised function in smooth muscle. In this context, it is of interest that a troponin C-like protein, which will restore calcium sensitivity to desensitised skeletal actomyosin, has been isolated from brain, fibroblasts and neurosecretory tissue, where it seems to modulate cyclic nucleotide turnover. (Amphlett *et al. FEBS Lett.* **72**, 163; 1976).

In the light of these new findings of calcium-dependent phosphorylation as the trigger for actomyosin ATPase activity in smooth muscle, it seems valuable to consider the possibility of myosin-linked regulation in skeletal muscle. A calcium-sensitive light chain kinase, distinct from that in smooth muscle, has been demonstrated in skeletal muscle, but no link between phosphorylation and actin-activated ATPase activity could be found (Perrie *et al. Biochem. J.* **135**, 151; 1973). There are suggestions that phosphorylation and the calcium response of skeletal myosin may be intimately related (Okamoto & Yagi *J. Biochem.* **80**, 11; 1976). Until recently, there was no *in vitro* evidence for calcium regulation by skeletal myosin. However, Lehman (*Biochem. J.* **163**, 291; 1977) has demonstrated that this can occur in some conditions.

All the evidence so far accumulated indicates the complexities of control mechanisms potentially available for the precise regulation of excitation–contraction coupling; an assessment of their physiological importance will provide a step further towards the seemingly ever-receding mirage of a complete understanding of muscular contraction. ☐

Cosmic ray age, soft X-rays and the galactic wind

from J. J. Quenby

ALTHOUGH the distribution of stars in our Galaxy is in the form of a thin disk, a strong flow of plasma perpendicular to the plane may produce a magnetic halo of near circular shape. Recent cosmic ray balloon measurements carried out by Webber, Lezniak, Kish and Simpson of the University of New Hampshire (*Astrophys. Lett.* **18**, 125; 1977) may provide data which aids the modelling of the phenomena involved.

Initial experimental observation of the presence of a galactic halo which follows the figure of an ellipsoid of revolution come from cosmic radio noise data at hundreds of MHz. Relativistic cosmic ray electrons, spiralling in weak, few microgauss or less magnetic fields, are thought to produce the radio noise by way of the synchrotron radiation process. The halo constitutes a possible magnetic reservoir for cosmic rays and these particles could therefore spend the greater part of their lives well outside the galactic disk.

A recent, dynamical argument for the existence of the halo has been put forward by Ipavich (*Astrophys. J.* **196**, 107; 1975). He starts from the idea that the anisotropic motion of cosmic rays along the interstellar magnetic field lines may generate and amplify magnetohydrodynamical waves by a scattering process, but the waves in turn lose energy to the interstellar gas. The net result is that cosmic rays heat the interstellar medium and a situation, analogous to the solar wind in the solar corona, may arise. An out-of-the galactic plane flow is initiated which eventually becomes supersonic in a manner similar to the sub to supersonic transition at the neck of a rocket motor nozzle. Gravity perpendicular to the disk plays the same part as the constriction in the motor nozzle. Hence interstellar field is carried out by this galactic wind to constitute an additional, low density medium reservoir for the cosmic rays.

Studies of the relative abundances of the cosmic ray isotopes (Li, Be, B) known to be produced by nuclear interactions in the interstellar medium suggest that the mean amount of matter transversed by the cosmic rays is $\sim 5\ \mathrm{g\,cm^{-2}}$. Taking this figure in conjunction with the $\sim 1\ \mathrm{cm^{-3}}$ number density of interstellar atoms implies a cosmic ray life of about 10^6 yr. An alternative and more direct measure of this life lies in finding the amount of radioactive ^{10}Be relative to its decay product ^{10}B existing in the cosmic ray flux. The 1.5×10^6 yr beta decay half life of this process is conveniently matched to the expected cosmic ray age. Spacecraft telescopes flown by Garcia Munoz *et al.* (*Astrophys. J. Lett.* **201**, L141; 1975) detected few or no ^{10}B particles, suggesting a most probable age $\sim 2\times10^7$ yr. These workers reconcile their age measurement with the order of magnitude smaller apparent value given by the Li, Be, B abundances by supposing that cosmic rays spend most of their life in the halo where the matter density may be one hundredth of that in the disk. Unfortunately, conflicting experimental evidence is available from a much larger, but balloon borne, detector flown by Hagen *et al* (*Astrophys. J.* **212**, 262; 1977) which recorded enough ^{10}Be to be consistent with an age of only 5×10^6 yr. Webber and coworkers have now performed a balloon experiment in a similar energy range to that of Hagen *et al.* but at a greater altitude so that fewer unwanted atmospheric interactions take place. Also this latest detector seems to achieve better mass resolution than that of previous balloon experiments. Webber *et al.* carefully consider the distortion effects of solar modulation on the relative ^{10}Be abundance (see *News and Views* **259**, 11; 1976) and find that the mean cosmic ray life must be at least 8×10^6 yr and could be 15×10^6 yr or more. They conclude that their data would allow either a disk or halo model for cosmic ray confinement.

Owens and Jokipii (*Astrophys J.* in the press) have set the halo model for cosmic ray motion within the context of Ipavich's work. They show that a cosmic ray age of more than 10^7 yr requires a halo scale height of 4 to 10 kpc and an average galactic out-of-plane wind velocity of $<60\ \mathrm{km\,s^{-1}}$, numbers consistent with Ipavich's estimates. It is interesting to note that Ipavich also requires an interstellar gas temperature in the 10^4 to 10^6 K range. Soft X-ray background survey data points to a hot galactic gas temperature $\sim 6\times10^5$ K as revealed by rocket measurements made by Levine and coworkers at MIT. Further insight into the dyanmics of a hot galactic gas can arise from a consideration of the X-ray emission from rich clusters of galaxies such as COMA. The soft X-ray line and continuum data on the

---

J. J. Quenby is in the Department of Physics at Imperial College, London.

COMA cluster are consistent with a model in which a hot, intercluster gas receives its energy from heating inside the individual active members of the cluster (see Serlemitsos *et al. Astrophys. J. Lett.* **211,** L63; 1977 for experimental data; Yahil *et al Astrophys. J.* **185,** 787; 1973 for theoretical discussion). Cosmic ray heating could well be the relevant non-thermal process feeding the intercluster medium through enhanced galactic winds. ☐

Forecasting in crop protection

from R. Hull and C. R. B. Baker

> The Second Conference on Forecasting in Crop Protection was held in Paris on June 21–24 by the European and Mediterranean Plant Protection Organisation.

THE ability to forecast reliably the timing and intensity of pest and disease attack on crops is crucial to reducing unnecessary and undesirable use of pesticides if at the same time agricultural productivity is to be maintained and improved. This claim was made for many national forecasting schemes described at the conference, which covered national forecasting organisations, meteorology, field monitoring methods for pests and diseases, interpretation of pest and disease counts, development of forecasts, and the link-up with the growers.

Schemes of varying sophistication were outlined. They ranged from a computer-based system organised by Michigan State University in the US, through national networks of observers and warning stations operated in countries such as France and Hungary, to systems designed to provide warnings of a specific pest or disease. Techniques on which forecasts are based include monitoring pests and diseases by sampling crops, trapping insects in pheromone traps and in tall suction traps that sample the migrant fauna in the air, observations on caged pests, observations on plots of appropriate crops maintained at regional forecasting centres and the use of meteorological data. In most countries such schemes are operated by government agencies or are subsidised by government funds. Since the activity of all organisms damaging crops is influenced in one way or another by weather, much attention was given to recording and interpreting meteorological data in relation to phytopathological problems.

Means of communication with farmers and growers included postal warnings, radio and television broadcasts, telephone answering services, public notices and personal contact. Although delegates seemed convinced that their own national schemes were making some impact on farming practice, especially in reducing use of pesticides, little quantitative evidence was presented that pests and diseases were being controlled more efficiently or that the forecasting schemes were economic. It was emphasised that forecasts were generally issued to cover a region and cannot be detailed enough to show the local variations that affect the individual grower. He needs local advice or further education so that he can make his own judgement based on the growth stage of his own crops and the actual stage and abundance of the pests or diseases present and also sometimes of their natural enemies.

Several speakers stressed the need for a thorough knowledge of the biology of pests and diseases, but important gaps in such knowledge were evident throughout the conference. In particular there was a lack of a coherent picture of differences in pest behaviour across Europe. Standardisation of assessment methods as recommended in the FAO manual on Crop Loss Assessment Methods was discussed.

Agricultural research and advisory services have been operating in most developed countries for several decades. It was clear from this conference that despite all the effort applied so far, problems in pest and disease management continue and that forecasting is an essential part of any ultimate solution. Unless flexible, the best devised research and advisory programmes could be nullified by a change in agricultural practice, such as that from ploughing to direct drilling.

The conference made two proposals for follow-up action under the aegis of EPPO. First, a working party should be convened to appraise the various systems of assessing and forecasting crop losses. Second, closer cooperation should be organised between meteorological and plant protection services in the collection, dissemination and use of meteorological observations in relation to the needs of crop protection. ☐

R. Hull has just retired as Director of Broom's Barn Experimental Station, Harpenden; C. R. B. Baker is an entomologist at the Plant Pathology Laboratory of the Ministry of Agriculture, Fisheries and Food at Harpenden.

Tree-ring dating in Britain comes of age

from a Correspondent

> The first International Symposium on Dendrochronology in Northern Europe was held at the National Maritime Museum, Greenwich, London from 11 to 14 July, 1977. The papers will be published by *British Archaeological Reports* (112, Banbury Road, Oxford OX2 7BP) in collaboration with the National Maritime Museum and the Research Laboratory for Archaeology and the History of Art, University of Oxford. A companion exhibition, instigated by Dr J. M. Fletcher (University of Oxford), on tree-ring analysis of Tudor portraits is open at the National Portrait Gallery, London until 18 September 1977.

IN the historic setting of the National Maritime Museum close by the Royal Observatory, Greenwich Park—long famous for the measurement of British Standard Time—the precise measurement of the annual growth rings of trees for dating purposes was shown at the meeting to be an interdisciplinary and international subject with great potential for European environmental science and archaeology. Dendrochronology, although not yet a commonplace technique, already is shedding light on such wide ranging subjects as past climates, sea level changes, tree ecology and forest management in prehistoric and historic times, and is proving an invaluable aid in dating of archaeological remains and in art history.

Holding the meeting in London was particularly important for until the past 10 years or so little research on tree-ring analysis has been done in Britain, although some pioneering work was done in the 1940s and 50s by Lowther and Schove. This slow start may be explained partly because of the difficulty of devising suitable reference chronologies for oaks growing in southern and eastern England, but also partly by unfamiliarity with the classical German and Russian work on the subject.

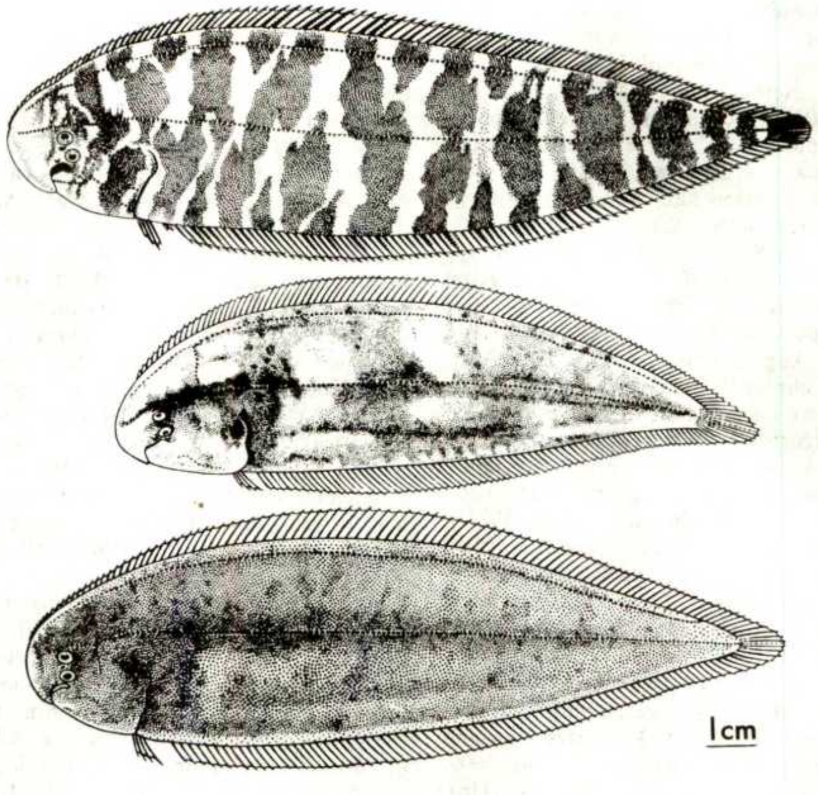
The problem in the development of tree-ring analysis in north-west Europe has been that the growth of deciduous trees and thus the pattern of annual rings is more variable in temperate regions than in the semi-arid and arid areas of south-west USA: site conditions (such as altitude, and soil), defoliation by insects and man's influence may affect tree growth in Europe as much as temperature and rainfall—the predominant

Tongue soles revised

from our Marine Vertebrate Correspondent

THE flatfishes are an interesting and important group of bony fishes: interesting because of their unique asymmetry which involves a complicated reordering of the head skeleton, eyes and optic nerves on metamorphosis; important because almost throughout the world they are of considerable value as food fishes. These two aspects have resulted in their being studied by workers in different disciplines possibly more than most comparably sized fish groups. Their systematic arrangement and taxonomy have been studied, notably by Norman in his *Systematic Monograph of Flatfishes* **1** (London, 1934) although he never completed the second volume which was to have included the families of true soles and tongue soles (Soleidae and Cynoglossidae).

To some extent this hiatus has partly been filled by a comprehensive revision of the tongue soles of the genus *Cynoglossus* by A. J. K. Menon (*Smithsonian Contributions to Zoology,* no. 238, 1–129; 1977). The Cynoglossidae are flatfishes which have a typical elongate body form, tongue sole being a most apt name. The dorsal, caudal, and anal fins are continuous around the edge of the body, other fins are reduced or absent, and the mouth is placed on the side of the head, in most species having a sinister curve about it. In the genus *Cynoglossus* the eyes are very small, close together and are always on the left side of the head. It seems that the reduction of the eyes is probably associated with the well-developed lateral line sensory system; in some species three lateral lines run along the length of the body while most have a complex of head lines. On the blind side, however; this sensory system is reduced or totally absent (a striking difference to the situation in the true soles which have a highly evolved sensory system on the eyeless side of the head). As Menon points out members of the Soleidae are mostly feeders on the surface of the sea bed, while the tongue soles are adapted to plough through the mud or sand on the bottom, hidden beneath the surface themselves, and feeding on buried food organisms. As an adaptation to this way of life the cynoglossids do not have the fin rays of the dorsal fin running forward to the extreme edge of the head (as do the soles) but the first dorsal pterygiophore, which in other fish would support the anterior fin rays, is modified to form a rostral cartilage. This rostral cartilage provides support for the thin, elongate snout which acts like a forward-pointing ploughshare as the fish slices its way through the seabed.



Three specimens of *C. puncticeps* showing variation in pigment pattern. Top from Kerala; others from Cochin.

Menon's revisionary study is, of course, basically a systematic work. He gives a brief discussion of the other genera in the family (*Symphurus* with forty or so species, *Paraplagusia* with only four species), and then detailed diagnoses of the forty-nine members of the genus *Cynoglossus.* All the species are illustrated by simple line drawings supplemented by photographs of most species. Menon's work thus means that in the future there will be an adequate source of identification available for these closely similar fishes.

The geographical distribution of these tongue soles has a number of points of interest. The centre of distribution lies in the eastern Indian Ocean–West Pacific area, especially around the Malay archipelago, where Menon finds the more specialised and rapidly evolving species complexes. Around the periphery of this region more primitive types are found, ranging from Japan to eastern Australia, and along the Indian Ocean coast of Africa. *Cynoglossus* is one of the few groups of fishes which are widespread in the Indo-Pacific and are found off the West African coast as well, although absent in the Western Atlantic. Most of the West African species belong to a large group of species (the *canariensis* group) which Menon regards as primitive and near to the ancestral stock. Menon's study thus has some interest in the evolution of this group of flatfishes and will be of value to zoogeographic studies although work in a broader field than at generic level will be necessary to evaluate some of his conclusions concerning relationships and distribution.

---

factors in arid and tropical countries —and so make it difficult in parts of northern Europe to devise reference curves for trees such as oak, beech and elm which all react differently to environmental conditions. In northern Europe too there is the added disadvantage that no tree has the longevity of the bristle-cone pine or sequoia although sessile oaks often live more than 500 years. Oak is the timber found most often in archaeological excavations.

Although the Russian, Shvedov, as long ago as 1892, related variations in annual ring width to rainfall, it was the German, Huber, who from the 1940s to his death in 1970, laid the foundations of the modern methodology and his influence remains in the rigorous work of J. Bauch and D. Ekstein (University of Hamburg) and B. Becker (University of Hohenheim) which sets standards for all other laboratories. Computer programs devised by Bauch and Ekstein now make it possible to cross-date local and regional tree-ring curves reliably. A master chart established for oak in the Netherlands dating back to AD 1036 synchronises with corresponding curves in southern and western Germany where, as Becker reported, there is now a master chronology from the present back to 717 BC.

In northern Germany and in the coastal region of the North Sea from Denmark past the Netherlands and Flanders to south-east England and East Anglia, however, the major German chronology does not usually apply and so independent curves have been constructed. For Haitabu in the Schleswig area of north Germany, where dendrochronology has been used to date the important Viking trading centre, Ekstein has established a chronology dating back to AD 400. In the Netherlands Bauch has found a second chronology, independent of his other, which covers the years AD 1109–1637. To this curve are related parts of eight overlapping chronologies, each about 300 years long and covering the period AD 514 to 1609, established by J. M. Fletcher (University of Oxford) for southern and eastern England.

Both Fletcher and Bauch have used a combination of excavated and architectural timbers and oak panels of paintings to make their reference curves. An added dimension to this work is its relevance to art history. In England, for example, oak panels were the common means of support for most portraits painted before 1620. By classifying 150 such paintings dendrochronologically, Fletcher has been able to gather information about panels from the same tree and to deduce the likely date to within 10–20 years of some of the portraits whose history is uncertain. Bauch, similarly, has studied over 200 Dutch and German paintings mainly of the seventeenth century.

Other chronologies for Britain are gradually being established. P. Leggett and A. Hibbert (Liverpool Polytechnic) are working on trees felled in woodland in North Wales and have a master chronology for oak running from AD 1711 to 1975 which cross-dates with one in Northern Ireland prepared by M. G. L. Baillie (Queen's University, Belfast). R. Morgan (University of Sheffield) is dating material excavated by J. Schofield (London Museum) from Roman and Mediaeval sites on the River Thames in London. Tree-ring analysis of this timber, recovered from old waterfronts, is helping to clarify discrepancies between the dates inferred from the stratigraphical position of artefacts found on the site and radiocarbon dating. Valuable topographical clues are also being obtained from the way the timber was used in the construction of the waterfronts, and changes in the environmental conditions around London from Roman to Mediaeval times can be suggested by study of the ring-widths of the oak timbers. When two species, oak and elm, are found together in Mediaeval excavations, then comparisons of their use and growth at a particular time have been made (D. W. Brett, Bedford College, London). In another part of England an oak chronology for the period AD 1635–1972 has been established for the Winchester area (A. C. Barefoot, North Carolina State University, and others) and this curve, when combined with ^{14}C dates and a separate chronology for earlier timber, is being used to date excavations in the city led by M. Biddle (Winchester Research Unit).

Across Europe in East Germany, M. Jährig (Akademie der Wissenschaften der DDR, Berlin) has examined pieces of timber excavated from Slavonic settlements dating from the 6th to the 10th centuries AD with the aim of establishing a master chronology for GDR. So far he has obtained a relative chronology for 492 years in this period in the central region of the country; a separate chronology will probably be needed for the northern region.

In Sweden, there is now a master chronology for oak for the past 1,400 years. Analysis of oak used to make coffins excavated from Mediaeval churchyards in Lund (T. S. Bartholin, University of Lund) is suggesting how the climax forest in that part of Scandinavia changed during the period AD 1000–1200. In the earlier coffins the oak boards are narrow ringed and range up to 500 years old; but by AD 1150 the oaks had few and broad rings, suggesting that by this date open woodland pasture had replaced the dense virgin forest.

Much earlier chronologies using timber and radiocarbon dates are being devised for the Somerset Levels, a wetlands area in south-western England where an extraordinary series of wooden trackways of various constructions have been excavated by an inter-university team led by J. M. Coles (University of Cambridge). A member of this team, B. J. Orme (University of Exeter), described how tree-ring analysis is being used to establish dates for the substantial oak planks and for the brushwood material of ash, hazel, alder and birch used in the building of the trackways which date from the fourth to the first millenium BC. Analysis of this worked wood at different sites has enabled the team to determine which woods were used for which purpose in the trackway structures, to show that woodland management by coppicing existed as long ago as the fourth millenium BC and to ascertain the durability and re-use of different timbers. Past environmental conditions can also be inferred from studies of the timber from different millenia.

Other applications of dendrochronology reported included a study of submerged forests around the British Isles by A. Heyworth (University College of North Wales, Aberystwyth) who is using tree stumps ranging in age from more than 8,000 years to less than 1,000 years as a measure of sea level changes. R. E. Tout and W. E. Gilroy (University of Surrey) are analysing concentrations of trace elements in tree rings: the technique offers a way of distinguishing the heartwood and sapwood boundary where this is unclear. The elements potassium, chlorine, and manganese seem useful as indicators.

Most dendrochronologists use measurements of ring width to prepare their reference curves. Another line of approach is to measure wood density by X-ray densitometry and two speakers, F. H. Schweingruber (Swiss Forest Research Institute, Birmensdorf) and H. Polge (Centre National de Recherches Forestières, Champnoux, France) believe that the technique is a better indicator than ring width of climatic changes in the past and is quicker to use. Schweingruber is using subalpine conifers (fir, spruce, pine and larch) to reconstruct the fluctuations in summer temperature in the Alps. S. J. Milsom and M. K. Hughes (Liverpool Polytechnic) are experimenting with X-ray densitometry on oak which seems to present more problems than pine although it is thought that the technique will be useful for dating wide ringed timber.

On the third day of the meeting, the point made by G. C. Varley (University of Oxford) that defoliation of oaks by caterpillars can have similar effects on tree growth as harsh weather led to lively discussion and reminded everybody that the wood they work with came from a living tree whose growth was influenced by a variety of quantifiable and unquantifiable factors, not forgetting drought, plagues of insects, sunspots and other 'Acts of God'. These may be 'noise' but should not be disregarded in constructing computer programs. Computers and statistics, although essential tools today, must be used discriminately; as several participants pointed out the human eye and brain remain indispensable for noting anatomical irregularities in timber and for the matching of tree-ring curves. □

Radio sources with superluminal velocities

**M. H. Cohen*, K. I. Kellermann†, D. B. Shaffer†, R. P. Linfield*, A. T. Moffet*,

A. Witzel‡, R. T. Schilizzi§ & B. J. Geldzahler||**

Radio data from four extragalactic sources, three quasars and one galaxy, show evidence for an apparent expansion faster than the speed of light. The data on these 'superluminal' sources are reviewed, and their implications briefly discussed.

BRIGHTNESS distributions in four extragalactic radio sources have been seen to vary so rapidly that the apparent transverse velocity of expansion is greater than the velocity of light (assuming a cosmological origin for the redshift). The term superluminal will be used to describe this phenomenon. In this paper we review many of the observations of superluminal expansions, and also add some new material. Blandford, McKee, and Rees[1] have summarised theoretical ideas on the subject.

The observations have all been obtained with very-long-baseline interferometry (VLBI) systems using two to five radio telescopes, spaced over thousands of kilometres, to form multi-element interferometers. Various model-fitting and map-making procedures have been used to estimate parameters of the brightness distribution, such as diameter, separation and flux of components, position angle, and so on. In some cases the data have been sufficiently accurate and extensive to warrant many-parameter models, and detailed contour diagrams have been made. In general, however, the models are not unique. Some have been challenged[2,3]; but there still is general agreement among different workers on the main features of the sources. VLBI map-making is presently in a stage of rapid development; in particular there is a growing use of phase data, and more definitive results are expected in a few years.

Four sources including three quasars (3C345, 3C273, and 3C279) and one radio galaxy (3C120) will be discussed. In each case we give simple angular measures and do not discuss the detailed models of brightness distribution. More complete discussions will be found in the references.

3C345 ($z = 0.595$)

Two observing groups[4,5] have independently shown that 3C345 could be accurately described as a simple double source in mid-1974. The two components were approximately Gaussian and contained most or all of the flux density at $\lambda = 2$, 2.8, and 3.8 cm. In these experiments three or four telescopes were used. The simple model was an excellent fit, and there was no requirement for, nor evidence of, a more complex structure. At most other epochs only two or three telescopes were used. The brightness distributions were not as well determined, of course, but a simple double fit the data and the separation, θ, was accurately determined in every case.

Figure 1 shows the separation of the centres of the two components as a function of time. The point at 6 cm is taken from a number of measurements made in 1968 and 1969 (ref. 8). The source was only slightly resolved at that early epoch and θ was determined from the best-fitting double. The position angle was assumed to be 105°, the value found more recently. The 3.8 cm point at 1971.1 (ref. 7) is similarly model dependent because the source is only partially resolved. The three points in 1976 are provisional because detailed model fitting is yet to be done; however, they are unlikely to change much because θ is well determined from the sharp minima of the visibility function.

The points in Fig. 1 show that the brightness distribution expanded by a factor of about 3 in 7 years, at the approximate

Fig. 1 Apparent separation of the two components of 3C345 as a function of time. The slope of the line is 0.17 marc s yr^{-1}. The observations at 2 cm are taken from ref. 5; the 2.8-cm points are from refs 5 and 6, and the four points in 1972–73 are from private communications with N. Broten and M. Quigley (the points in 1976 are discussed in the text); the 3.8 cm points are from refs 4 and 7; and the 6-cm point is discussed in the text. ×, 2.0 cm; ●, 2.8 cm; ○, 3.8 cm; ▲, 6.0 cm.

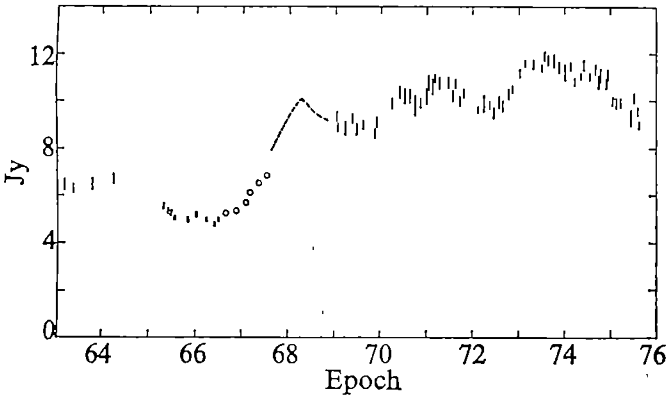

Fig. 2 Total flux density of 3C345 at $\lambda = 3.8$ cm. Points from 1963 to 1966.5 are taken from ref. 10; from 1966.6 to 1967.5, ref. 11; 1969.0 to 1971.6, ref 12; 1971.6 to 1974.4, ref 13; 1974.4 to 1975.6 from private communications with W. A. Dent, and the dashed line is interpolated between observations at 2.8 and 4.5 cm reported in ref. 14.

rate 0.17 marc s per year. The expansion may not be uniform, however, for the slope seems to be flatter in 1972–73, and steeper in 1975–76. The difference in slope explains most of the discrepancy in the rates already reported in the literature[8, 9]. The angular rate can be converted into an apparent transverse velocity at the source by multiplying by the cosmological distance and correcting for time dilation with a factor (1+z).

$$\frac{v}{c} = \frac{\theta}{H_0 q_0^2 (1+z)}\left(q_0 z + (q_0 - 1)[(1+2q_0 z)^{\frac{1}{2}} - 1]\right)$$

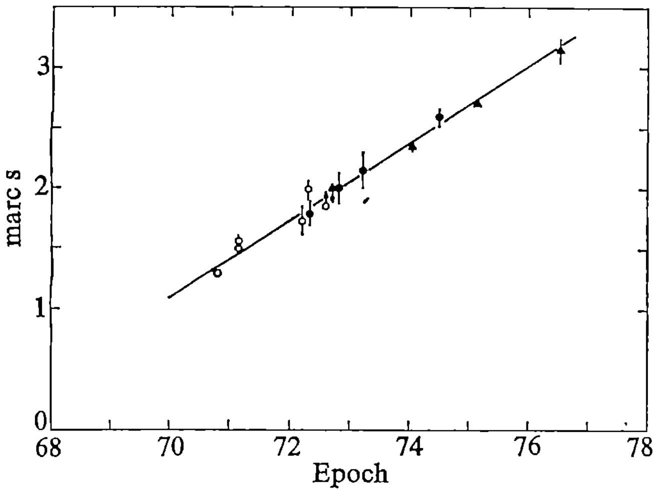
The line in Fig. 1 corresponds to $v/c \approx 7$. ($H_0 = 55$ km s^{-1} Mpc^{-1} and $q_0 = 0.05$.)

The angular separation of the components of the double seems to be independent of wavelength over at least an octave. However, the detailed visibility curves show that the ratio of flux densities varies with wavelength; that is, the components have different spectra.

The position angle (PA) of the double was determined for all cases shown in Fig. 1 for which there were adequate data. There are no substantial differences with wavelength or time; the PA has been constant at 105°±3°.

Extrapolation of the rate shown in Fig. 1 to zero separation indicates that an 'event' occurred in 1966. Figure 2 shows the total flux density of 3C345 at 3.8 cm. A major increase in flux density began in 1966; the flux doubled in two years and has since stayed high. The near coincidence of the times suggests that the outburst and the expansion have a common origin.

Fig. 3 'Size' of 3C273, where size $\theta^* = (2w)^{-1}$ and w is the distance to the first minimum of the visibility function. The slope of the line is 0.32 marc s yr^{-1}. The observations at 2.8 cm are taken from refs. 15 and 16 and the points at 3.8 cm are taken from refs 7 and 17–19. The 6-cm points are our previously unpublished data. ●, 2.8 cm; ○, 3.8 cm; ▲, 6.0 cm.



3C273 ($z = 0.158$)

3C273 has a complex elongated structure (refs 3, 15 and 16 and W. D. Cotton *et al.*, in preparation). Its low declination (2°) means that the (u,v) coverage is poor and the models are more indeterminate than for high declination sources like 3C345. In consequence, different authors have proposed models of different character, some expanding with time[7,15], and others with stationary components whose intensities are suitably varied[3,17]. All observers agree that the overall size of the brightness distribution increased from 1971 to 1974, but the uniformity and nature of the increase has been argued.

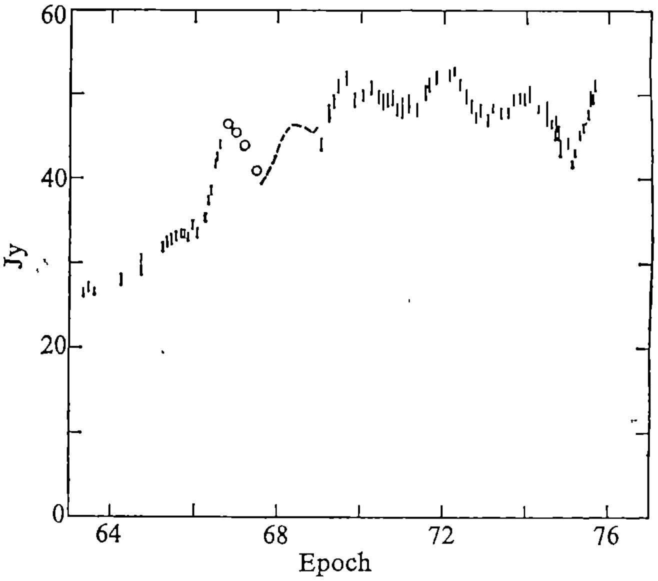


Fig. 4 Total flux density of 3C273 at $\lambda = 3.8$ cm. References for the points are as in Fig. 2.

Figure 6 of Schilizzi *et al.* (ref. 15) shows a succession of (u,v) diagrams with the observed lines of maxima and minima of the visibility function. The lines are not equally spaced; therefore, the source cannot be represented by a simple (that is, Gaussian) double. Furthermore, the relative spacings change with time, and successive sets of lines move toward the origin. This means that the shape changes with time, and that, in some measure, it is increasing in size. The visibility data shown by Schilizzi *et al.*, however, do not define the brightness distribution uniquely.

In an attempt to escape difficulties caused by modelling with inadequate data, we have studied one simple measure of the overall size, the distance from the origin to the first minimum of the visibility function. Let w (in wavelengths) be this distance, then $\theta^* \equiv 1/(2w)$ is the angular separation of the components if the source is a simple double. In the more general case where the source consists of several isolated components strung out on a line, θ^* is a good measure of the overall angular scale. For example, in a wide range of triples which we studied numerically, θ^* varies from 1.0 to 0.65 times the overall size.

We plot θ^* at various epochs in Fig. 3. Many of these observations were taken on only one baseline, and the position angles were very poorly determined. So, to provide a consistent basis for calculating θ^*, we assumed PA = 64° in all cases. This is the typical value obtained when multi-baseline data are available, although the source is known to be nonlinear[3,16]. The error bars in Fig. 3 come from the uncertainty in estimating the locations of the minimum, and do not include any errors from an incorrectly assumed position angle. The arrows in mid-1972 signify lower and upper limits.

Further data exist at 2.8 cm for 1975 and 1976, but the character of the visibility function is different then from what it was earlier. The functions do not contain any clearly recognisable extrema (except at the origin), but drop rather smoothly to a 'core' value. The brightness distributions may still contain 'components', but all (or perhaps all but one) of them must be large enough to be individually resolved at the interferometer spacings which would otherwise produce maxima and minima. In contrast, at 6 cm the structure still had concentrations which could produce the observed minima. These recent results will be discussed separately.

The 2.8-, 3.8-, and 6.0-cm data all fit together very well up to 1975. We conclude that the basic shape was independent of wavelength over this range, although there were spectral differences in component intensities.

The overall size of the brightness distribution increased rather steadily and more than doubled in 6 years. The word 'expansion' may properly be used to describe this behaviour. The points in Fig. 3 cluster around a line with slope $\theta^* = 0.32$ marc s per year ($v/c = 4.2$). If the line is extrapolated it hits zero in 1966. The total flux density at $\lambda = 3.8$ cm is shown in Fig. 4, and, again, the 'expansion' starts, roughly, near the beginning of a large sustained increase in flux density.

3C120 ($z = 0.033$)

3C120 varies rapidly in flux density and appearance, and has been observed frequently in an attempt to follow its variations[7,15,21-25]. Although many of the observations have been rather incomplete, in several cases very good data were obtained with 3 or 4 telescopes, and simple double models fit very well. The best of these cases comes from our observations at 2.8 cm in 1976.1, when 5 well defined maxima and minima were observed using telescopes at Green Bank, Fort Davis and Owens Valley. As with 3C345, a well-separated Gaussian double accurately fit all the visibility data. However, the compact structure in 3C120 never produced nearly all the total flux, the way it did in 3C345. The compact components of 3C120 are embedded in a larger, undetermined structure.

In all cases with good data the PA was near 65°. To determine a size in the poorer cases, we assumed that a double was always a reasonable representation of the source; and, when necessary, we also assumed PA = 65°

The separation of the two components of the double is plotted in Fig. 5 for all values in the literature (with exceptions noted below) together with some of our previously unpublished data at 2.8 and 6.0 cm. The parentheses indicate cases where there was ambiguity; typically, the source was only weakly resolved, or the size determination was made from a single minimum on one baseline, or the first minimum was not directly observed.

We recognise two major epochs of expansion in Fig. 5, and have indicated them with straight lines whose slopes correspond to $v/c = 5$ and $v/c = 8$. At 1974.5 the 3.8 and 2.8 cm observations showed doubles of very different separation. No unique interpretation can be given for this, for the size and strength of the components of the doubles are very poorly determined. The observed double structure did not account for the total flux at either wavelength, so it is possible that both doubles existed at both wavelengths but were not recognised because of the differing resolutions. Thus, the close-spaced double seen at 2.8 cm might not have been recognised at 3.8 cm because its first minimum would have come at 1.9×10^8 wavelengths, whereas the maximum length of the baseline was only 1.0×10^8 wavelengths. Similarly, at 2.8 cm where the minimum length of the baseline was 1.6×10^8 wavelengths, components larger than about 1.5 marc s would have been resolved, and this double would have been missed. Spectral differences of the type apparently seen in 3C273 would increase the size of the outer components at 2.8 cm and accentuate this behaviour.

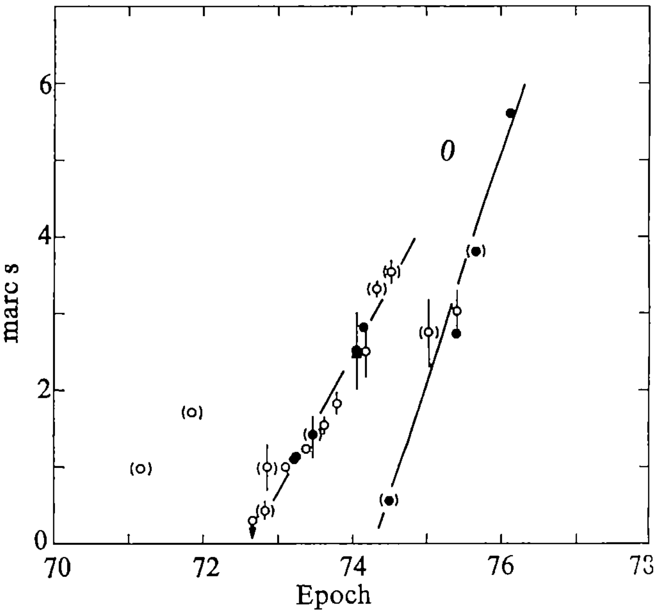

Fig. 5 Separation of the two components of 3C120, assuming a double at PA = 65° when necessary. The slopes of the lines are 1.8 and 2.9 marc s yr^{-1}. The early observations at 2.8 cm are from ref. 15, and the points from 1974.5 on are previously unpublished. The 3.8-cm data are from refs 7, 15, 21-25. The 6-cm point at 1974.5 is previously unpublished. ●, 2.8 cm; ○, 3.8 cm; ▲, 6.0 cm.

The points in 1971 were once interpreted as evidence for a superluminal expansion[21], but that result is ambiguous with only two points. Further data exist for early 1972 (refs 22, 23), but they are not plotted. The visibility was changing rapidly then, but remained very low. Therefore, the strong concentrations which must have existed in 1971 had dissipated, and by 1972.3 most of the flux came from regions greater than about 1 marc s in diameter.

During both epochs of expansion the PA was near 65° whenever a good model could be generated.

Fig. 6 Total flux density of 3C120 at $\lambda = 3.8$ cm. Points from 1969 to 1971.6 are taken from ref. 12; 1971.6 to 1974.4, ref. 13; 1974.4 to 1975.6, from private communications with W. A. Dent, and the dashed line is interpolated between observations at 2.8 and 4.5 cm reported in ref. 14.

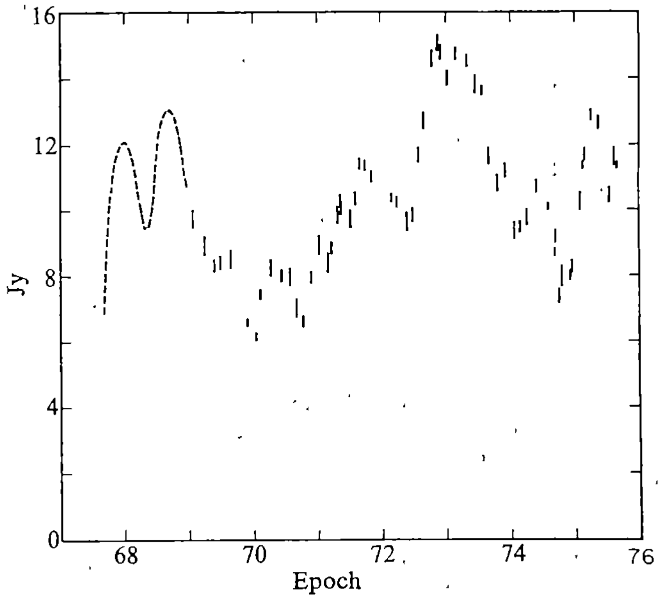

Table 1 Strong compact extragalactic radio sources

Source	Name	Id	z	$S_{3.8}$ (Jy)	VLBI	Refs
0316+41	3C84	G	0.018	20-58	slow variable	15, 24, 25, 27, 28
0355+50	NRAO150			7.3-15	stable double (?)	16, 24, 29
0430+05	3C120	G	0.032	6.4-15.1	superluminal	
0923+39	4C39.25	Q	0.699	8.5-11.8	stable double	5, 24, 29
1226+02	3C273	Q	0.158	28-53	superluminal	
1253−05	3C279	Q	0.538	11.2-17.5	superluminal	
1641+39	3C345	Q	0.595	8.8-11.9	superluminal	
2134+00		Q	1.94	11.0-13.4	slow variable	15, 24
2200+42	BLLac	G	0.07	4.8-14.2	rapid variable	16, 24, 29, 30
2251+15	3C454.3	Q	0.859	9.0-20.2	variable core	16, 24, 26, 29

Figure 6 shows the total flux density of 3C120 at $\lambda = 3.8$ cm. This source varies more rapidly and has a greater fractional variation than 3C345 and 3C273. The largest outburst in Fig. 6 begins in mid-1972 and is coincident with the start of the first expansion shown in Fig. 5. The second expansion starts in early 1974 and does not appear to be correlated with any exceptionally large flux event.

3C279 ($z = 0.538$)

The available data on 3C279 are mainly at $\lambda = 3.8$ cm, from the period 1970–73 (refs 7, 17–20, 26). Most of this material is from only one baseline, and the interpretations are ambiguous.

The two earliest observations have been interpreted as an expanding double, with separation rate $\dot{\theta} = 0.27$ marc s yr^{-1} ($v/c = 10$) (refs 7, 19). The rate is not well determined with only 2 points, but it is consistent with observations at 6 cm in early 1972 (ref. 17), which give the overall size as about 2 marc s. A minimum in the 13-cm visibility function on baselines from California to Australia[26] near the beginning of 1970 is also consistent with a simple double model based on the 3.8-cm observations, suggesting that the separation of the two components was similar over that range of wavelengths.

A sequence of observations at 3.8 cm in 1972 (ref. 17) can be interpreted as a new expansion event, since an unresolved weak core was seen in March and April 1972, and this became substantially resolved by November 1972. Another possibility is that all the 1972 data came from a triple source whose overall dimensions were constant, but whose component flux densities varied[17]. The published material is consistent with either model, and further data are necessary to discriminate between them.

Interpretatations

It is of interest to ask what fraction of all sources are superluminal, and whether statistical arguments can be made for or against any of the customary interpretations. These are difficult questions because adequate surveys do not exist at the short centimeter wavelengths, and VLBI surveying is particularly incomplete. However, we can make some comments.

At $\lambda = 3.8$ cm, 3C345 is the weakest known superluminal source, with mean flux density $<S_{3.8} \sim 10$ Jy during the expansion. We know of 15 extragalactic sources which have been as strong as 10 Jy at 3.8 cm, at any epoch. Five of these are radio galaxies with most of the flux coming from extended regions. (3C123, 3C353, Vir A, Cen A, Cyg A). The remaining 10 sources are shown in Table 1. The fifth column in Table 1 gives the known range of flux density at $\lambda = 3.8$ cm. The sixth column gives a comment on the structure seen with VLBI, and the seventh column gives references for those sources not discussed in detail above.

3C84 has several components which vary in flux density but seem to have little motion. NRAO150 has been observed less than the others and its size is less than 0″.001 so that intercontinental observations are necessary for reasonable resolution.

4C39.25 has a well-defined double structure with constant separation, but the total flux density is variable. 2134+004 apparently is more complex than a simple double, and has slow weak variations in its brightness distribution. BL Lacertae has a double structure which is variable but keeps a constant position angle. The observed changes in BL Lac are not systematic as in the superluminal sources, but it may well be that shorter sampling intervals are required to see them, as this is the most variable source in Table 1. 3C454.3 has a core-halo structure. The variations in total flux density follow those of the unresolved core.

Nearly half the strong compact sources show a superluminal effect. This suggests that mechanisms which require us to be in an especially favourable position are unlikely to be at work. Luminous relativistically moving clouds are one such class, because to see them superluminally we have to be within a small solid angle[1]. However, the blue-shift of the approaching clouds also raises the possibility of a selection effect. Perhaps superluminal sources seem common partly because the blue shift raises their flux density above the minimum level being counted. To study this possibility we need to know the distribution of superluminal sources with flux density, which is unknown at present.

The superluminal sources all show a systematic expansion, and at least one of them shows two epochs of expansion with the same PA. This argues strongly against mechanisms which basically are random and allow both expansions and contractions. Gravitational lenses and some other propagation and opacity effects are of this type. So, too, would be a collection of separated sources which are independent, and flash at random times. Propagation and opacity effects also are unlikely because they predict that the separation would be wavelength dependent, contrary to observation.

The fact that the superluminal effect has been seen in a galaxy as well as in three quasars suggests that it cannot be used as evidence against a cosmological origin for the redshifts.

Thus what is now known can be summarised as follows. Nearly half the strong ($S_{3.8} \geq 10$ Jy) compact ($\theta < 0''.01$) sources show a superluminal expansion at centimetre wavelengths, and changes in overall size of up to factor 10 in periods of one to two years have been observed.

No systematic contractions have been seen. The separation of components in a source is basically independent of wavelength from 2 to 6 cm, although the components may have different spectra. In 3C273, and perhaps in 3C120, we may have observed an epoch where component evolution produced different sizes at different wavelengths.

The position angle is substantially constant during an expansion. In at least one case (3C120) there have been two distinct epochs of expansion. The position angle is the same for both.

The brightness distribution does not expand uniformly, but there is an overall trend as shown in the graphs. The epoch of zero separation, determined by extrapolation of the trend, may be close to the start of a major outburst in flux density.

The extensive data for 3C345 at 1974.5 and for 3C120 at 1976.2 strongly suggest a structure which can be represented as a simple double, with the two components being approximately equal. 3C273 is more complex. There are both simple (4C39.25) and complex (3C84) sources which do not show variations in the overall size of the brightness distribution although their total flux densities vary on time scales similar to those for the superluminal sources.

We thank W. A. Dent, and the members of the Canadian-British and the MIT-NASA VLBI groups, for giving us data in advance of its publication, and for useful comments. M.H.C. and J.D.R. are grateful to the Institute of Astronomy, Cambridge, for their hospitality during the period when part of this study was made.

This work was supported in part by grants from the US National Science Foundation. J.D.R. is a US National Science Foundation Graduate Fellow.

Percolation theory of residual phases in porous media

R. G. Larson, L. E. Scriven & H. T. Davis

University of Minnesota, Department of Chemical Engineering and Materials Science, Minneapolis, Minnesota 55455

When one fluid displaces another by flow through a porous medium, the fraction of pore space occupied by trapped residual phase correlates with the ratio of viscous to capillary forces in the flow. This dependence, heretofore unexplained, is derived from the mechanics of fluid blobs, the nature of pore structure, and percolation theory. Pore space topology is shown to be as important as geometry in the statistical flow behaviour of large populations of fluid blobs in two-phase flow in porous media. Topology and geometry can each be modelled usefully by a single parameter characteristic of the pore space.

WHEN porous solids, whether unconsolidated such as powders, granulated solids, soils, and clastic sediments, or cemented and often diagenetically altered, such as bones, sintered solids and sedimentary rocks, have their pore space occupied by two immiscible fluid phases at least two connectivity domains of the non-wetting phase can be observed. In one—'the continuous regime'—the phase is largely self-connected over the range of many pore diameters, and in the other—the 'blob regime'—the phase exists only as discrete, disconnected 'blobs' surrounded completely by the other phase[1]. The wetting phase, of course, can also exhibit continuous and discontinuous regimes, but these will not be considered here.

The saturation of a phase is defined as the fraction of pore space or void space occupied by that phase. It is observed in flow experiments that when a non-wetting phase in the continuous regime is drained to a saturation below some critical value (about 0.1–0.5 (ref. 2), depending on the fluids) by the flow of a second, wetting, phase, the former phase breaks up into discrete blobs. In this blob regime, the non-wetting phase is much more difficult to displace from the porous medium. There has previously been no satisfactory theory of these facts, nor of related phenomena of capillary pressure and relative permeability, although some of the elements for the explanation have been available. These constitute blob mechanics and are reviewed and extended here. They are then tied together with new elements from percolation theory. The synthesis makes it plain that the topology and randomness of the pore space are important. In this article, we show how these aspects influence residual saturation.

In typical porous media, a fluid at a given saturation in the continuous regime flows with flow rate proportional to the applied pressure gradient (Darcy's Law[1]) even for very low pressure gradients. A fluid phase in the blob regime, however, does not flow at all at a given pressure gradient, if γ, the interfacial tension between the two phases, exceeds a certain critical value.

This contrast is easily explained by reference to the Young–Laplace equation for the pressure jump across an interface between static fluids

$$\Delta p = \gamma\left(\frac{1}{R} + \frac{1}{R'}\right) \qquad (1)$$

where R and R', the principal radii of curvature of the interface, are, for fluids in a solid matrix, complicated functions of pore geometry and the contact angle which the interface makes with

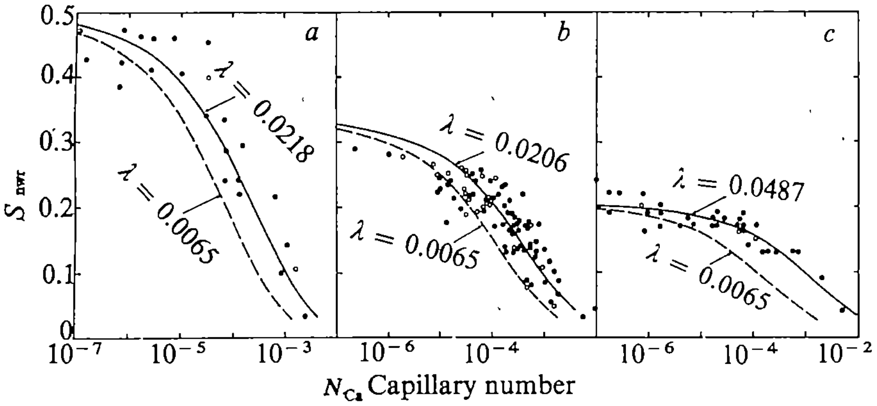

Fig. 1 Residual non-wetting phase saturation as a function of capillary number, experiment and theory. *a*, Foster and McMillen's data, $\sigma = 2$; *b*, Abram's data, $\sigma = 3$; *c*, Lefebvre du Prey's data, $\sigma = 5$.

the pore wall. Nevertheless, R and R' are of the order of D, a characteristic pore diameter of the medium; thus

$$\Delta p \sim \frac{\gamma}{D} \tag{2}$$

For typical values of γ (30 dyne cm^{-1}) and D (10^{-4} cm) Δp is of the order of 3×10^5 dyn cm^{-2}, or about a third of an atmosphere. A blob in static equilibrium in a typical porous medium at ordinary values of γ can, therefore, develop large pressure differences across its interfaces. If equation (1) holds at least approximately during slow flow, then with such large pressure differences, disconnected blobs fail to flow because they easily adjust their meniscus configurations to withstand low imposed pressure gradients. According to blob mechanics, the adjustments required are greater the longer the blob is in the flow direction. Hence, longer blobs are more readily mobilised than shorter ones. These predictions have recently been confirmed experimentally for the first time[3].

Residual saturation should thus also depend on the distribution of blob lengths, which is a consequence of the way in which the continuous regime breaks down into the blob regime. Because this process seems to be governed by randomness of the pore space, we adopt the hypothesis that the size distribution of blobs is that of one material randomly mixed with another within a space which is conveniently approximated as network-like or tree-like. Applied to this hypothesis percolation theory yields the needed size distribution. The resulting predictions of residual saturation agree with extensive experimental data hitherto unexplained.

Blob mechanics

Imagine a blob trapped in a porous sample surrounded by continuous fluid which is under an imposed average pressure gradient, dp/dx. In what conditions will this blob be mobilised? To answer this precisely, requires finding the conditions in which the given fixed-volume blob can find no configuration which satisfies the Young–Laplace equation and the boundary conditions imposed by the geometry of the pore space it is in. To identify these conditions approximately, we observe that the viscous flow of continuous fluid around the motionless blob develops a pressure difference, $\Delta p_{\text{avail}} \simeq l dp/dx$, across its length, l, in the flow direction, which is available to drive the blob forward. The pressure difference necessary to dislodge the trapped blob, Δp_{nec}, is given approximately by $\Delta p_{\text{nec}} = \alpha\gamma/D$, where α is a dimensionless constant which depends on the geometry of the trapping pore space. The blob is mobilised when

$$\Delta p_{\text{avail}} \geq \Delta p_{\text{nec}} \tag{3}$$

and the minimum blob length, l^*, required for mobilisation, is given by the condition $\Delta p_{\text{avail}} = \Delta p_{\text{nec}}$, which can be rewritten as

$$l^* \simeq \alpha\gamma/D \left(\frac{dp}{dx}\right) \tag{4}$$

Now dp/dx is proportional to the continuous phase fluid velocity, v_w, according to the extension of Darcy's Law which accounts successfully for two-phase flow[1]

$$v_w = \frac{k_{rw}K}{\mu_w}\left(\frac{dp}{dx}\right) \tag{5}$$

μ_w is the continuous phase fluid viscosity; k_{rw} its relative permeability at the specified saturation, and K the permeability of the porous medium, so that

$$l^* = \left(\frac{\gamma}{v_w}\mu_w\right)\frac{\alpha k_{rw}K}{D} \tag{6}$$

A reasonable approximation which has proved useful for many porous media is[4]

$$D \simeq \beta\sqrt{K\varphi} \tag{7}$$

where φ is the porosity of the medium and β is a dimensionless constant. Letting $n^* \equiv l^*/D$, a dimensionless blob length, gives

$$n^* \simeq \lambda\left(\frac{\gamma}{v_w\mu_w}\right)k_{rw}\varphi \tag{8}$$

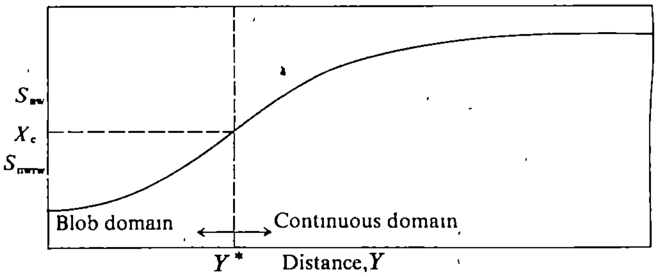
where $\lambda \equiv \alpha/\beta^2$. If only continuous phase is flowing, $v_w = v$, the superficial velocity, and

$$n^* \simeq \lambda N^{-1}{}_{Ca}\, k_{rw}\varphi \tag{9}$$

where $N_{Ca} \equiv v\mu_w/\gamma$ is a dimensionless ratio of viscous mobilising forces to capillary trapping forces.

An analysis of this sort was also made by Melrose and Brandner[2], who derived our λ in terms of pore geometry and

Fig. 2 Schematic saturation profile in a porous medium at a point in time during displacement of a non-wetting phase.



blob configuration. Using estimates which they reported from experiments on unconsolidated packs of uniform, nearly-spherical glass beads or sand grains, we find an approximate value for λ is 0.0065. This microscopic theory of blob mobilisation, following Melrose and Brandner, predicts that for a given blob there is a critical capillary number above which it cannot remain in static equilibrium, a prediction confirmed by experiments with individual blobs[3].

Blob population dynamics

The theory of the relationship between the mechanics of individual blobs and the flow behaviour of large populations of them has been missing. Their collective, macroscopic flow behaviour has been investigated experimentally, however. The results show a correlation between the capillary number, N_{Ca}, appearing in equation (9) and S_{nwr}, the residual non-wetting phase saturation which is irremovable at the given flow conditions no matter how much driving fluid is flushed through the solid matrix. Several investigators[2,5-9] reporting on a large number of experiments using a wide variety of fluids in porous media, have shown that at values of N_{Ca} less than about 10^{-7}, S_{nwr} is a constant in the range 0.2–0.5. As N is$_{Ca}$ increased past a value in the range 10^{-7} to 10^{-5} (different investigators report different values) S_{nwr} begins to decrease. As N_{Ca} is increased further, S_{nwr} continues to decrease and eventually reaches zero at a value of N_{Ca} between 10^{-3} and 10^{-2}. McMillen and Foster's[9], Abrams'[5], and Lefebvre du Prey's[8] experimental data for this capillary number correlation are shown in Fig. 1.

The theory of the relationship between the mechanics of individual blobs and the statistical flow behaviour of large populations of them is supplied, we believe, by percolation theory. We advance here a simple version which predicts the capillary number correlation just described. Before proceeding to it, a brief explanation of percolation theory is needed.

Percolation theory

Many transport processes can be successfully idealised as transport of an abstract fluid through an abstract medium. Diffusion of a solute through a solvent is an example: the fluid (solute) can be imagined to flow randomly, and the process is termed a diffusion process. If, on the other hand, the fluid flow paths are determined by the medium, but the medium itself is in some sense random, the process is called a percolation process. This classification and the introduction of percolation theory are due to Broadbent and Hammersley[10].

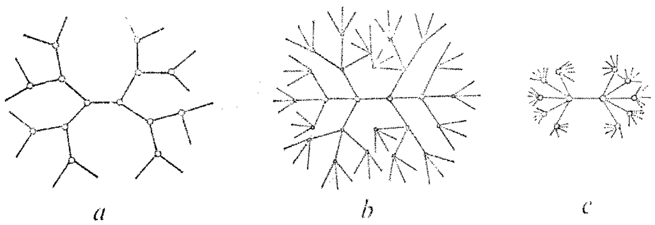


Fig. 3 Examples of Bethe lattices: $a, \sigma = 2$; $b, \sigma = 3$; $c, \sigma = 5$.

As a simple example, illustrating those features of percolation theory of relevance here, consider a very large, essentially infinite sheet of non-conducting material divided into identical square cells. At random, we replace a fraction of the cells containing the non-conductor with cells containing a conductor. If the fraction is small, most of the conducting cells occur as monomers—with no conducting cells as nearest neighbours. In particular, there is no continuous path of conducting cells long enough to span the sheet and, therefore, the sheet as a whole is non-conducting. As we increase the fraction of conducting cells, however, dimers, trimers, and larger clusters of connected conducting cells appear, until at some critical fraction, there appears an infinite cluster spanning the sheet. At this critical fraction, X_c, called the percolation threshold of the medium, the sheet becomes a conductor.

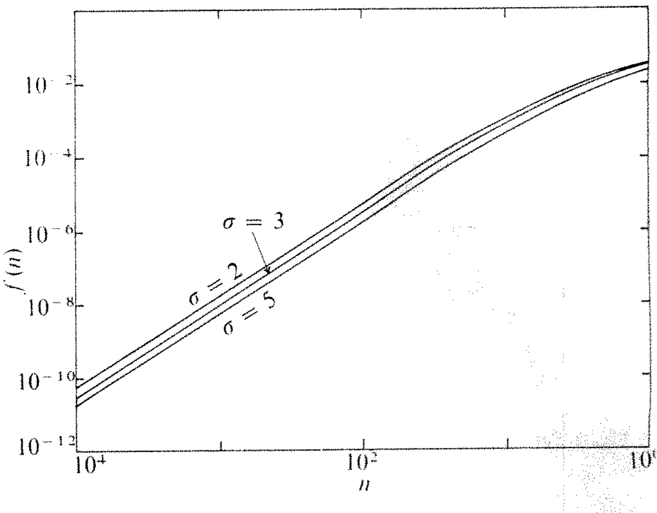

Fig. 4 Cluster size distribution function for a Bethe lattice.

Experiments with large two-dimensional (2-D) square arrays, such as the one described above, reveal an empirical X_c of 0.5 (ref. 11). That is, at least half the cells must be conducting, if the sheet as a whole is to show a non-zero conductivity. Three-dimensional (3-D) mixtures of conducting silver and non-conducting Bakelite show a conductivity threshold of 30 vol. % ($X_c = 0.3$)[12]. Small spheres of nickel mixed randomly with larger spheres of polyvinyl chloride and then compressed together to compaction show $X_c = 0.10$ (ref. 13). Computer studies of regular networks of chaotically distributed conductors and insulators yield percolation thresholds X_c ranging from 0.1 to 0.6, depending on the randomness of the distribution and connectivity of the network[11]. A computer-simulated 3-D continuum model gives $X_c = 0.29$ (ref. 14). Using percolation concepts, equation (9) which holds for an individual blob will now be used to derive a theoretical capillary number correlation.

Theory of residual phases

Imagine a one-dimensional 'waterflood', a process in which continuous non-wetting phase is being displaced from a porous medium by wetting phase. At a given time, the nonwetting phase saturation profile in the medium at some instant is represented by Fig. 2. At large Y (distance from position of wetting phase injection) the non-wetting phase is in the continuous regime, but at $Y = 0$, the non-wetting phase is in the blob regime, since only wetting phase is flowing. At some intermediate position, $Y = Y^*$, the non-wetting phase passes from the continuous to the blob regime. If the flow of non-wetting phase through the medium is such that at a given position Y, the nonwetting phase is distributed in a manner that leaves it randomly self-connected, then Y^* is the position where the non-wetting phase saturation, S_{nw} equals X_c, the percolation threshold for the void space of the solid matrix; that is, where S_{nw} is just low enough that the non-wetting phase no longer maintains long range continuity.

According to equation (9), if the capillary number of the flow is vanishingly small, as in very slow flow, then only long—essentially infinitely long—blobs will be mobile; that is, only that non-wetting phase which is in the continuous regime will flow. Thus, saturation must exceed $S_{nw} = X_c$ for non-wetting phase to flow if N_{Ca} is very small. Let waterflood residual non-wetting phase saturation be defined as

$$S_{nwrw} \equiv \lim_{N_{Ca}\to 0} S_{nwr}(N_{Ca})$$

then $S_{nwrw} = X_c$. Experimentally, as N_{Ca} becomes small, S_{nwr} asymptotically approaches S_{nwrw}, whose value typically lies between 0.2 and 0.5, as compared with a value of X_c of 0.25–0.30 for a completely random 3-D medium.

If, however, N_{Ca} is not infinitesimally small, then all blobs

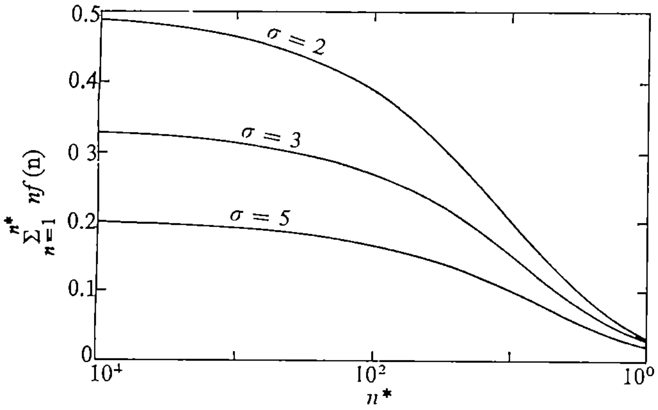

Fig. 5 Partial sum of the Bethe lattice cluster size distribution function.

of non-wetting phase longer than n^*, as given by equation (9), will flow, blobs shorter than n^* being trapped. When S_{nwr} decreases through $S_{\mathrm{nwr}} = X_{\mathrm{c}}$, the non-wetting phase breaks up into discontinuous blobs. Imagine that the distribution of projected lengths of these blobs is given; call it $f(n)$. That is, $f(n)$ is the expected number of blobs of length n in a large porous sample, divided by the total number of pores in the sample. The fraction of pore volume occupied by trapped blobs of length n is approximately $nf(n)$. (Here we ignore the difference between the number of pore bodies a blob occupies and its projected length, in pore diameters, along the direction of the pressure gradient.) On average, the volume of non-wetting phase trapped per pore volume, which is the residual non-wetting phase saturation, at a given N_{Ca} is

$$S_{\mathrm{nwr}} = \sum_{n=1}^{n^*} nf(n) \qquad (10)$$

where $n^* = \lambda\, N_{\mathrm{Ca}}{}^{-1} k_{\mathrm{rw}}\varphi$, as at (9).

If $f(n)$ were available a theoretical S_{nwr} (N_{Ca}) could be calculated from equations (9) and (10). If the already mentioned hypothesis is correct and the non-wetting phase is distributed in such a manner that it is randomly self-connected, then $f(n)$ may be obtained from a cluster size distribution for a 3-D random medium, a 2-D analogue of which was described above. A convenient approximation to such a medium, for which an analytical expression for the cluster size distribution is available, is the Bethe tree, or Bethe lattice. A Bethe lattice is a collection of bonds and sites, $\sigma+1$ bonds per site, illustrated in Fig. 3 for $\sigma = 2,3$, and 5. Let a fraction, X, of the bonds be conducting, the balance being non-conducting. Fischer and Essam[15] give an analytic expression for the size distribution of conductive clusters in a Bethe lattice; the distribution depends on σ and X. They find that the percolation threshold is at $X = X_{\mathrm{c}} = 1/\sigma$. In Fig. 1, the values of S_{nwrw}, and hence of X_{c}, can be seen to be about 0.5, 0.33, and 0.2, respectively, for Abrams' Berea sandstone, Foster and McMillen's Dalton sandstone, and Lefebvre du Prey's sintered teflon porous samples.

To model the topology of these porous media by Bethe lattices, one should take $\sigma = 2,3$, and 5, respectively, for the three media. The value of σ chosen to fit the value of S_{nwr} for a given porous medium is, in theory, a measure of the connectedness of the pore space of that medium. Higher values of σ indicate more inter-pore connections per pore, and thus a larger number of pathways one or more of which can be conductive to non-wetting phase.

With $X = X_{\mathrm{c}} = 1/\sigma$, $f(n)$ can be calculated from the analytic expression for Bethe trees in which $\sigma = 2,3$, and 5, respectively, with results shown in Fig. 4. Taking partial sums to get S_{nwr} as prescribed by equation (10) gives the results shown in Fig. 5.

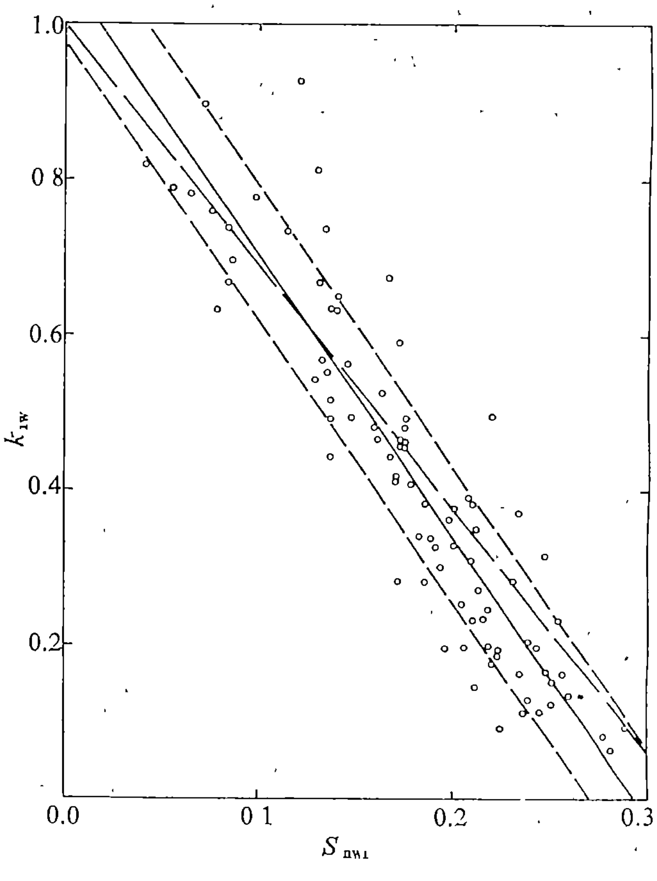
For his Dalton sandstone sample, Abrams[5] obtained for the relative permeability k_{rw} needed in equation (9), the experimental dependence on S_{nwr} shown in Fig. 6. This dependence is nearly linear over most of the range of S_{nwr}. By definition $k_{\mathrm{rw}} = 1$ at $S_{\mathrm{nwr}} = 0$, and experimentally $k_{\mathrm{rw}} = 0.06$ at $S_{\mathrm{nwr}} = S_{\mathrm{nwrw}}$ for Abrams' Dalton sandstone sample. A straight line between these two endpoints falls within a standard deviation of the least squares linear fit to the data (Fig. 6). Lacking the complete relation between k_{rw} and S_{nwr} for the other two porous media, we take as an estimate for all three media a straight line through the endpoints, the endpoint at $S_{\mathrm{nwr}} = S_{\mathrm{nwrw}}$ being provided by experiment for each porous medium.

For a given residual non-wetting phase saturation S_{nwr}, n^* can be found from $f(n)$ and equation (10), that is from Fig. 5; $k_{\mathrm{rw}}(S_{\mathrm{nwr}})$ can be found from the endpoint linear estimate; φ from experiment; and thus N_{Ca} can be calculated from equation (9) for a specified value of λ. There are two parameters: besides λ, which represents the relevant geometry of the pore space (introduced before equation (4) and at equation (7), there is behind $f(n)$ the topological parameter σ which we take as 2, 3 and 5, respectively, for the three porous media in Fig. 1. For λ we have tested various numbers: the value of 0.0065 based on Melrose and Brandner's estimates; and best-fit values of 0.0218 for Foster and McMillen's data, 0.0206 for Abrams' data, and 0.0487 for Lefebvre du Prey's data. The theoretical relations are plotted as S_{nwr} against N_{Ca} in Fig. 1*a–c*. The fitted λ's for the three consolidated porous media considered are consistently higher than the 0.0065 estimate for unconsolidated porous media. The difference is probably significant despite the uncertainties in Melrose and Brandner's estimates and the simplifying assumptions of the percolation theory employed here.

Conclusions

The relationship between residual non-wetting phase saturation and the capillary number of wetting phase flow in Fig. 1 is

Fig. 6 Relative permeability as a function of residual non-wetting phase saturation for Abram's Dalton sandstone sample. ———, Least squares linear fit; – – –, ± one standard deviation; — — —, endpoint linear approximation used in the theory.



successfully predicted from the mechanics of blob mobilisation and the percolation theory of transport. Central is a percolation concept of the size distribution of conductive clusters when conducting bonds are randomly located in a lattice. The clusters model the blobs of residual phase. Their size distribution depends on the connectivity properties of the lattice. These properties model the topology of the pore space. Geometry of the pore space dictates the relation between the size of a blob and critical flow conditions for mobilisation of that blob A practical implication of the theory is to reduce the problem of two-phase flow in porous media in first approximation to determining two parameters. One, the scale factor λ in this report, characterises the pore-geometry-dependent resistance to passage of a meniscus separating the phases. The other, the connectedness measure σ here, characterises the pore-topology-dependent number of alternate routes of meniscus passage. Concepts from percolation theory also lead to successful explanations of capillary pressure and relative permeability data from porous media[16,17].

An 8,000-yr palaeoclimatic record of the 'Double-Hale' 45-yr solar cycle

Rhodes W. Fairbridge

Department of Geological Sciences, Columbia University, New York 10027

Claude Hillaire-Marcel

Departement des Sciences de la Terre, Université de Quebec à Montreal, Canada.

A series of isostatically-emerged Holocene beach ridges on the east side of Hudson Bay have been precisely surveyed and dated back to 8,300 BP. *They number 185 and show a nearly uniform rhythm of about 45 yr correlated here with the 'Double-Hale' solar magnetic cycle. (Time is in sidereal yr.) Longer correlations are suggested with eustatic sea-level curve and with planetary conjunction cycles. The coupling mechanism with terrestrial meteorological behaviour is believed to be by means of stratospheric generation of polar cirrus cloud and low-latitude ozone, affecting the planetary albedo.*

A CONTINUOUS sequence of 185 Holocene, radiocarbon-dated raised beach lines on the eastern side of Hudson Bay, Canada, have a 45±5-yr cyclicity that reflects storminess and high tide crescendos (Fig. 1). The strandlines have been precisely measured by theodolite surveys and followed by helicopter and air photograph studies along the coast. They can be observed as far as Ungava Bay (Hillaire-Marcel). They have been known since the seventeenth century but have only now been surveyed[1,2]. The beaches have been dated by radiocarbon analyses back from the present to 8,300 yr BP (sidereal) when the 'Tyrrell Sea' began to appear as a result of deglaciation during the Flandrian transgression. The relative uniformity of the 185 emerged beaches suggests a regular dynamic mechanism. Thus 8,300/185 = 44.86, conveniently rounded to 45. If the beach ages are plotted at 45-yr intervals, they are found to correspond closely to the radiocarbon dates.

A complicating factor is introduced by the unfortunate mid-Holocene departures of the radiocarbon chronology from sidereal time which tend to distort those ages to lower values, but these systematic errors are in part counteracted by comparable errors introduced by old carbon from freshwater dilution.

The uniformity of the 45±5-yr cyclicity is implied by the mean uniformity of beach widths, but their heights become progressively greater as one goes back in time because of an exponentially decaying isostatic curve. The present rate of uplift is 1.1 cm yr^{-1}, but around 7,000 to 8,000 BP it was ranging through 5–10 cm yr^{-1}, and is thus comparable with the behavior of the Baltic Shield in the Gulf of Bothnia[4].

The beaches are so sharp and clearly preserved due to a happy coincidence of genesis and history. Their materials were partly eroded and redeposited in ice-foot conditions, which is a much more energetic process than normal long-shore drift. Further, the continuous isostatic uplift rapidly takes each beach up above the reach of storm waves and wind-driven ice floes, so that they are preserved in their pristine state. The climate maintains a continuous permafrost beneath a sparse cover of arctic tundra vegetation. There is no human interference with their natural state.

A strandline of this sort is preserved in the topography only at certain moments in time, when, for example, $dI+dE\to 0$ where dI is isostatic uplift over a given interval, dt; and where dE is eustatic rise. When they are both in phase, and moving at the same rate, the shoreline will remain constant long enough for a recognisable beach to form. A second mechanism for beachridge formation is during cycles of increased storminess when seasonal onshore winds briefly imitate the effect of a eustatic rise.

Inasmuch as the isostatic factor has a very sluggish rate of velocity change (maximum 1 cm yr^{-1} in 100 yr), compared with eustatic factor ($\approx$ 1 cm yr^{-1} in 1–10 yr), any systematic differences between the isostatic uplift curve and the actual height of a given series of beach ridges must reflect an anomalous eustatic oscillation.

By constructing a glacioisostatic crustal recovery curve and carefully measuring the anomalous high and low series of beach levels, it was, therefore, possible to distinguish a eustatic factor from the isostatic, in the manner already demonstrated for Hudson Bay by Andrews[5]. Some of the early beaches are today uplifted to a maximum of 315 m.

Comparison of the eustatic residual with earlier versions of the Holocene eustatic curve obtained from low-latitude situations[5] shows an interesting degree of coincidence. It is clear that sudden drops or rise of sea level of the order of 2–5 m are worldwide in effect and may occur within time spans of 100–200 yr (dE = 1–5 cm yr^{-1}). These negative sea-level oscillations cor-

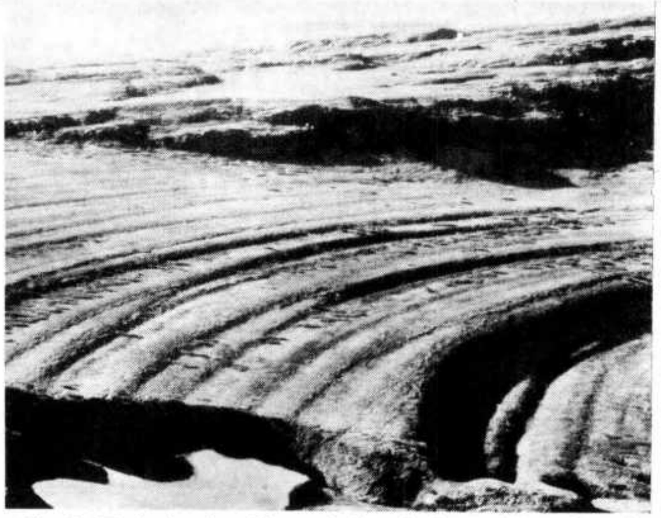

Fig. 1 Typical series of isostatically raised strandlines situated in Richmond Gulf on the eastern side of Hudson Bay, Canada. The sand-gravel beaches are well-preserved by permafrost and recur with a great regularity at around every 45 yr, representing cycles of storminess. A higher ridge, like that in the right foreground, represents a modification introduced by the eustatic factor, in this case a sharp regression followed by a rise, but not enough to overcome the isostatic emergence rate.

relate with documented climatic cooling and are assumed to be glacioeustatic (Fig. 2).

This fact can have a profound significance on climate prediction. If $dE = 1$ cm yr^{-1}, the equivalent ice volume is 4×10^3 km^3. The record shows that several cold spells sufficient to generate 1–2×10^6 km^3 of ice within one or two centuries have actually happened within the recent history of man in the present (Holocene) interglacial climatic conditions. The total ice volume of Greenland today is less than 2.6×10^6 km^3, equivalent to $dE\simeq6$m. Approximately 20 cold spells, each sufficient to generate at least 1×10^6 km^3 of excess glacier ice (above the global equilibrium level), have occurred during the last 6,000 yr, thus about one per 300 yr. No obviously predictable cyclicity is apparent.

The 45-yr cycle of storminess

The normal climate of the Hudson Bay is continental arctic, commonly rather calm and mild in summer and frigid in winter. Westerly storm tracks usually pass to the south. When, however, they periodically reach the latitude of Hudson Bay considerable wave action leads to rapid longshore drift and beach-building. The beach ridges were first attributed to these storms by Captain L. Foxe in 1631.

Because of the steady isostatic uplift (over 1 cm yr^{-1}) it is unlikely that after a 45-yr interval a new cycle of storms will cause the younger beach accumulation to overwhelm the earlier one. Thus the 185 beach lines preserved seem to represent a true record of somewhat regularly spaced meteorologic events. These are modulated, with larger and smaller beaches, by the glacio–eustatic factor mentioned above. A comparable but non-uplifted sequence of beach ridges on the Alaskan Arctic coast is attributed to meteorologic pulses related chronologically to the sunspot cycle[7].

Such a regular succession of climatically related geomorphic phenomena cannot be easily explained away by any steady state or stochastic hypothesis and invite a search for an exogenetic (cosmic) cause. The solar cycle seems to be the most obvious candidate. In recent years, it has been demonstrated with a reasonable degree of certainty that the sunspots are in some way expressions of solar climate that is tidally induced by planetary allignments[8]. If this is correct, two problems have to be considered: first, which of the planetary conjunctions or other configurations seem to have the leading role? And secondly, what is the mechanism of energy transfer from solar tidal behaviour to terrestrial climate?

If the second question is not met in some way the first does not become irrelevant, but in order to test the probability of the second, the timing of the first-named problem can possibly provide some guidance.

Solar tides

The timing of the basic '11-year cycle' is known to fluctuate between about 9 and 13 yr, but it is statistically around 11.1–11.3, thus close to that of the jovian yr, 11.8 sidereal yr. Equally, or more important, are the periods of other smaller but closer gravitational bodies affecting the Sun, notably Venus, Mercury and the Earth–Moon pair[8]. As with oceanic tides the problem of solar tides is quite complex.

The three-century record of closely observed sunspot behaviour is highly informative. Clearly the 22-yr heliomagnetic or Hale cycle is perhaps more significant than the familiar 11-yr pattern, and a study of the peak sunspot numbers (maxima) discloses a fourfold repetition of the 11-yr sequence, usually within a progressive rise to a crescendo every 45 yr (that is 40–49 yr, the so-called Double Hale cycle). Turning points (minima) were 1699, 1744, 1784, 1833, 1877, 1923, 1964 (ref. 9). A multiple (the King-Hele cycle) around 178–180 yr, gives the turning points in the long term sunspot series.

If one considers the less precise but historically quite well documented sunspot record of the Chinese[10] it becomes clear that there were lengthy periods with few sunspots (those observable without telescopes). The great sunspot dearth of the middle ages is particularly well known. In the record of planetary motions, the year AD 1433 is particularly significant, being the zero check year: with all planets in conjunction[11]. It is thus feasable to mark out various longer cycles from this date in order to see what terrestrial phenomena, if any, seem to match them[12]. The next significant planetary conjunction should be AD 1982.

Sidereal and radiocarbon years

Care should be taken to remember that the astronomical conjunctions are usually listed in terms of sidereal years, whereas much of the Holocene geological record is documented in radiocarbon years, which as mentioned earlier, have variable values. While at the beginning of the Holocene (10,000 yr BP), according to the varve-record, the departure was probably only of the order of ±200 yr, the middle Holocene was marked by errors in the radiocarbon age of 800 or even 1,000 yr, appeared too young[13,14].

The problem has to do with solar wind interacting with the earth's magnetic field which, as Bucha[15] has shown, has been weakening within the period of precision observation. This causes fewer cosmic rays to be deflected and thus more radiocarbon is generated. Accurately counted tree-ring samples indicate that between 200 and 700 BP there was a ^{14}C flux up to 2% above normal and thus dates in this period are up to 60 yr too young. Back to about 3,000 BP there were minor fluctuations, with some dates too old, but during the mid-Holocene there was a systematic departure giving dates too young by up to 800 yr (around 6,500 BP). The short term departures can also cause problems, because statistical peaks in site dates[15] may be artificially amplified; while the groupings almost certainly have a geomorphic–climatogenic cause, the possibility of ^{14}C flux variations should always be tested using tree-ring or varve standards, if possible.

An interrelationship between geomorphic–climatogenic events (such as eustasy, glaciation) and terrestrial magnetism is proposed by Olaussen and Svenonius[17]. It is significant that they correlate ice-loading and water-load distribution with reversals and predicted a magnetic reversal for some stage during the Flandrian transgression. A Gothenburg Event around 13,750–12,350 BP has, in fact, been widely recorded[18,19]. It could be expected that briefly during such a reversal there would be a regular deluge of radiocarbon over the whole Earth that for a few centuries might introduce seriously young dates.

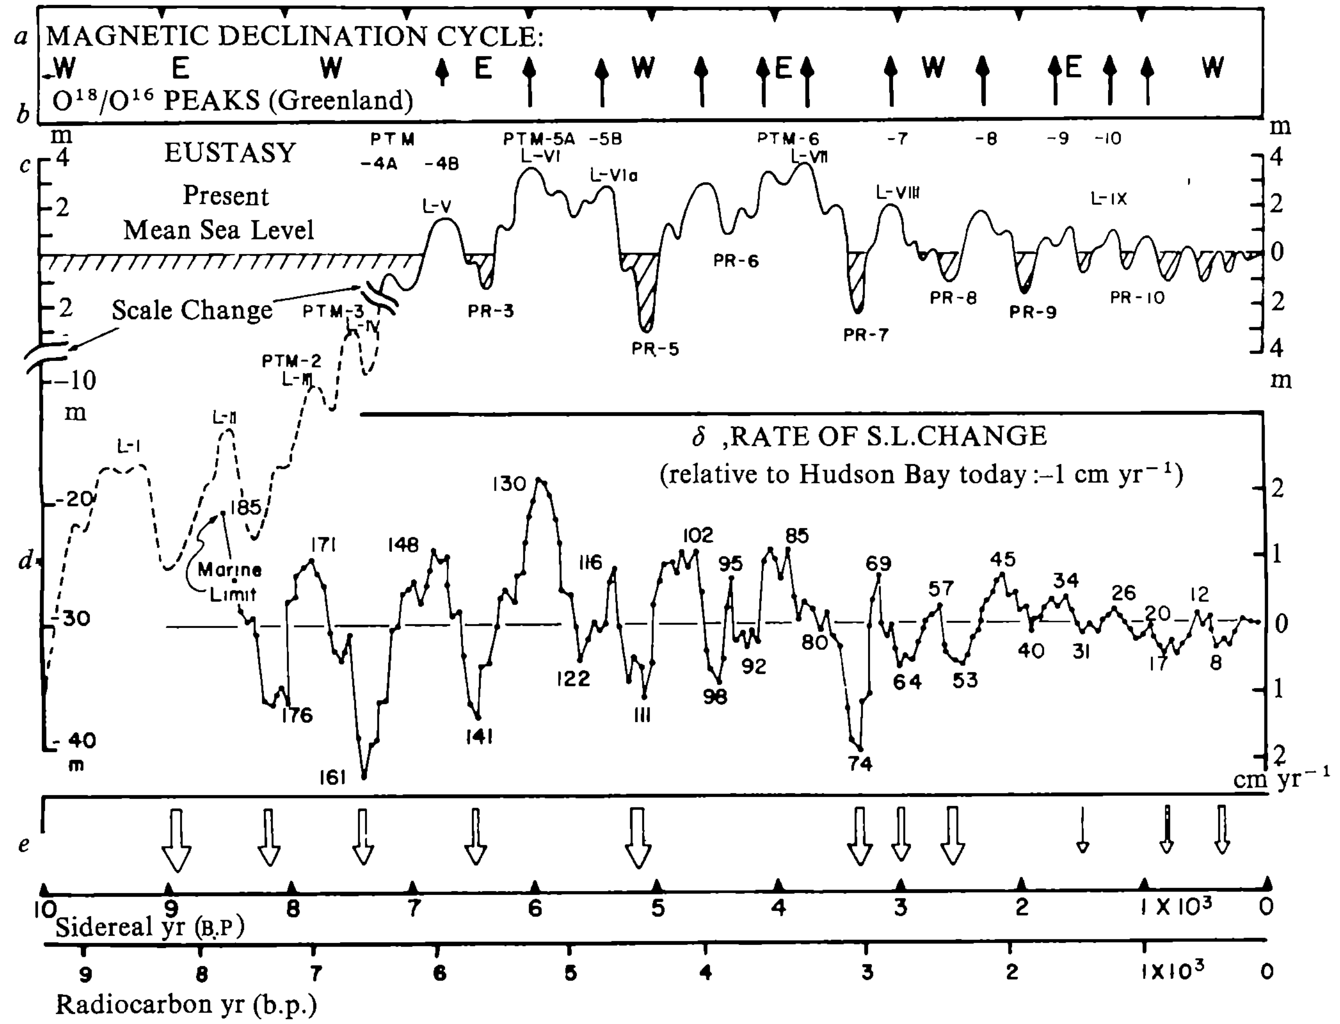

Fig. 2 Five records of 10,000 yr Holocene climate indicators compared. *a*, Magnetic declination cycle[33]: times of E–W inflections seem to represent times of lowest latitude (continental) sites for the magnetic pole, the present site being close to Hudson Bay, while the intermediate passage is over the ocean. (Question: does this have a climatic triggering effect?). *b*, The $^{18}O/^{16}O$ isotope peaks, as indicated by the Camp Century ice core from Greenland[35]. ^{18}O increases correspond to warmer fluctuations and to highest eustatic sea levels in the tropical oceans[36]. (Note: although there has been criticism and revisions of this record, the younger part shown here is not affected by the modifications and is apparently consistent for our own data shown below). *c*, Eustasy. This curve represents a slight updating of the Fairbridge Curve of 1961[30] and 1976[6], adjusted to sidereal time. Essentially, it represents a statistical summation of geomorphic sea-level traces (beach ridges, inter-tidal facies, coral in growth position) dated by radiocarbon. No adjustments are made for postglacial hydro-isostatic loading effects. PTM 1/10 peaks are based on Mörner's[36,37] Postglacial Transgression Maxima in S.W. Sweden. L-I/IX are Tooley's[38] Lytham raised beach levels from N.W. England. A comparable but younger series from New Zealand[39], and numerous other compatible records (Ters, Greensmith, Berglund, Martinsson), are omitted to avoid clutter. PR 1/10 are Mörner's Postglacial Regression Maxima. *d*, Delta, E, the rate of sea level change, as determined by Hillaire-Marcel[1,2] relative to the present-day east coast of Hudson Bay. Here the approximate crustal rise today is 1 cm yr^{-1} and the record, with the isostatic variability removed, now indicates rates of sea-level rise and fall. The inflection points (of no change) are numbered according to a continuous set of 185 numbered beach ridges on Hudson Bay, dating back 8,300 yr (sidereal). The relatively uniform geomorphic spacing of the beach ridges suggests a cyclicity of ~ 45 yr in storminess on Hudson Bay. *e*, Glacial advances. Major advances of mountain glaciers are known from radiocarbon dating of distal moraine belts, as recently summarised by Denton and Karlen[40] and others. Material is taken mainly from Alaska, Greenland, Scandinavia (Lapland), Patagonia and New Zealand: main advances occur simultaneously in both hemispheres. An almost identical set of dates was independently obtained at the same time from the Alpine glaciers by Patzelt[41]. Size of arrow is scaled to reflect magnitude of advance.

Little ice ages

It is not suggested that a regularly recurring minor planetary event of this sort can initiate an ice age condition. On the contrary, even the massive effects of the Milankovitch procession-tilt-orbital, now widely accepted[30–32], cannot generate glaciation phases on an earth that is not palaeogeographically prepared, which requires a blocked oceanic circulation and an asymmetric distribution of major continental land areas in one hemisphere, to create climatically sensitive latitudes. Only 10% of all geological time has thus been favourable to ice ages, and within an ice age of perhaps 2–10 × 10^{6} yr only 10% of that time is occupied by runaway glacial advances of continental dimensions (Pleniglacials). The rest of the time is filled by interglacial or stadial/interstadial climates. Nevertheless, it would only take a minor temperature departure for a few centuries in the north of Britain to trigger another glacial stage in the present sensitive state of global climatic instability. What is needed to explain little ice ages of a few centuries or less is, therefore, merely a small climatic pulse.

The critical year AD 1433 was first brought to attention by Pettersson[33] who believed that it correlated with catastrophic tides and flooding. In fact, the oceanic tidal effect of planetary conjunctions is quite minor, but the solar tidal response may have been quite different. This AD 1433 is the all-planetary conjunction, the so-called zero-check year. From Schove's long term Chinese sunspot evidence and other data, the year 1433 coincided by a remarkable high but short-lived period of sunspot activity, and after a brief but dramatic rise (to the > 150 spot level) there was a second sunspot dearth (Maunder Minimum) at the same time attended by a major rise in ^{14}C

flux (ref. 25 and P. E. Damon). Historical climatic analyses[26-28] show that 1433 initiated a time of great instability, culminating in the great medieval little ice age, with its attendant human suffering. It seems that the conjunction time coincided with a high sunspot state, which immediately followed by a low-spot condition indicates a minor glacial event.

Accordingly, taking AD 1433 as the base year, the major planet conjunctions have been traced back through the Holocene. Several years ago, a first attempt at this was made by Stacey[11], but at that time it was limited by interpretations and errors in the radiocarbon record. He attempted to correlate the planetary periods with the Fairbridge eustatic curve, assuming the fluctuations of the latter to represent (inversely) the rise and fall of glaciation. What has come out from the more recent studies of the Holocene eustatic record[30,31] is that the negative fluctuations that correlate with glacier advances and little ice age conditions are very brief events within a rather mild interglacial climatic pattern. The negative sea-level fluctuations are of the order of 3–5 m. In the last 8,000 yr there have been seven of these major departures; they show up equally in the tropical eustatic curve, in the Hudson Bay beach ridge curve and in numbers of glaciological and marine sedimentological curves. They are rather evenly spaced and despite difficulties in establishing their sidereal dates mentioned above, their regularity is striking. It was therefore considered that the seven recurrences of the 1,134-yr planetary conjunction stadial cycle should be seriously considered as being involved in providing a trigger mechanism.

With the reservations mentioned earlier concerning radiocarbon chronologies (apart from geological field errors) we would, nevertheless, like to draw attention to both the 567-yr and 1,134-yr astronomical cycles (major planets in conjunction). Going back from AD 1433 (= 517 BP), the turning points on the 1,134-yr cycle were 1,651, 2,785, 3,919, 5,053, 6,187 and 7,321 BP (sidereal) years. The hemicycle years (the 567-yr sequence) were 1,084, 2,218, 3,352, 4,486, 5,620, 6,754 and 7,888 BP.

Equally important in all probability is the solar activity tidal cycle (King-Hele) of 178–179 years. The Camp Century (Greenland) ice core showed both this and the 80-yr Gleissberg Cycle. It appears in the major Hudson Bay anomalies and various other records.

Certain coincidences are rather compelling: the great mid-Holocene glacial readvance (known in all glaciated regions), and identified in world oceans with a 6-m drop in sea level (PR-5 of the Baltic and beach 111 of Hudson Bay), coincides precisely with the fourth cycle back from AD 1433, that is, at 5,053 BP. It also matches the 25th cycle back of the 178–180-yr King-Hele cycle. Other dates are less than compelling. At present, we can only say the results look interesting.

Rhodes Fairbridge is indebted to the Humboldt-Foundation (Bonn-Bad Godesberg) in awarding him an Alexander von Humboldt Prize together with a stipend that supported a six-month sabbatical at the University of Köln (Germany) (1976–77), and lecture tours ranging from Uppsala to Budapest where these ideas were tested and refined. Claude Hillaire-Marcel's research was supported by grants from the National Research Council of Canada and the Centre d'Etudes Nordiques of the Université Laval, Quebec.

The size of Rous sarcoma virus mRNAs active in cell-free translation

Tony Pawson*, Robert Harvey & Alan E. Smith

Department of Molecular Virology, Imperial Cancer Research Fund, Lincoln's Inn Fields, London WC2, UK

Sedimentation analysis of mRNA from RSV-infected chick cells suggests that Pr76, the precursor to the virus structural proteins, is synthesised on a mRNA of similar size to virion RNA, whereas a protein with molecular weight 70,000 tentatively identified as the non-glycosylated precursor to the viral glycoprotein, gp85, is synthesised on a smaller size class of mRNA.

ROUS sarcoma virus (RSV) contains a genomic virion 70S RNA which in denaturing conditions dissociates into two apparently identical 30–40S RNA subunits[1-5]. We and others have translated RSV virion 30–40S RNA in cell-free systems derived from mammalian cells[6,7]. The major *in vitro* product of RSV virion 30–40S RNA is a polypeptide similar, if not identical, to the 76,000 molecular weight precursor to the group-specific (gs) antigens, Pr76, which is found in RSV-infected cells[6-8]. Pr76 synthesised *in vitro* in response to RSV virion 30-40S RNA can be labelled with *N*-formyl-methionine derived from the initiator tRNA, fMet-tRNA_F. Since fMet can

*Present address: Department of Molecular Biology, University of California, Berkeley, California 94720.

only be incorporated at the N terminus, this result indicates that the N-terminal end of Pr76 arises directly from an initiation event and not as a result of cleavage of a larger molecule. Since all other active initiation sites on eukaryotic mRNAs seem to be near the 5′ end of mRNA molecules, we interpret this result to mean that the gene for the gs antigens is located at the 5′ end of the viral RNA (ref. 6).

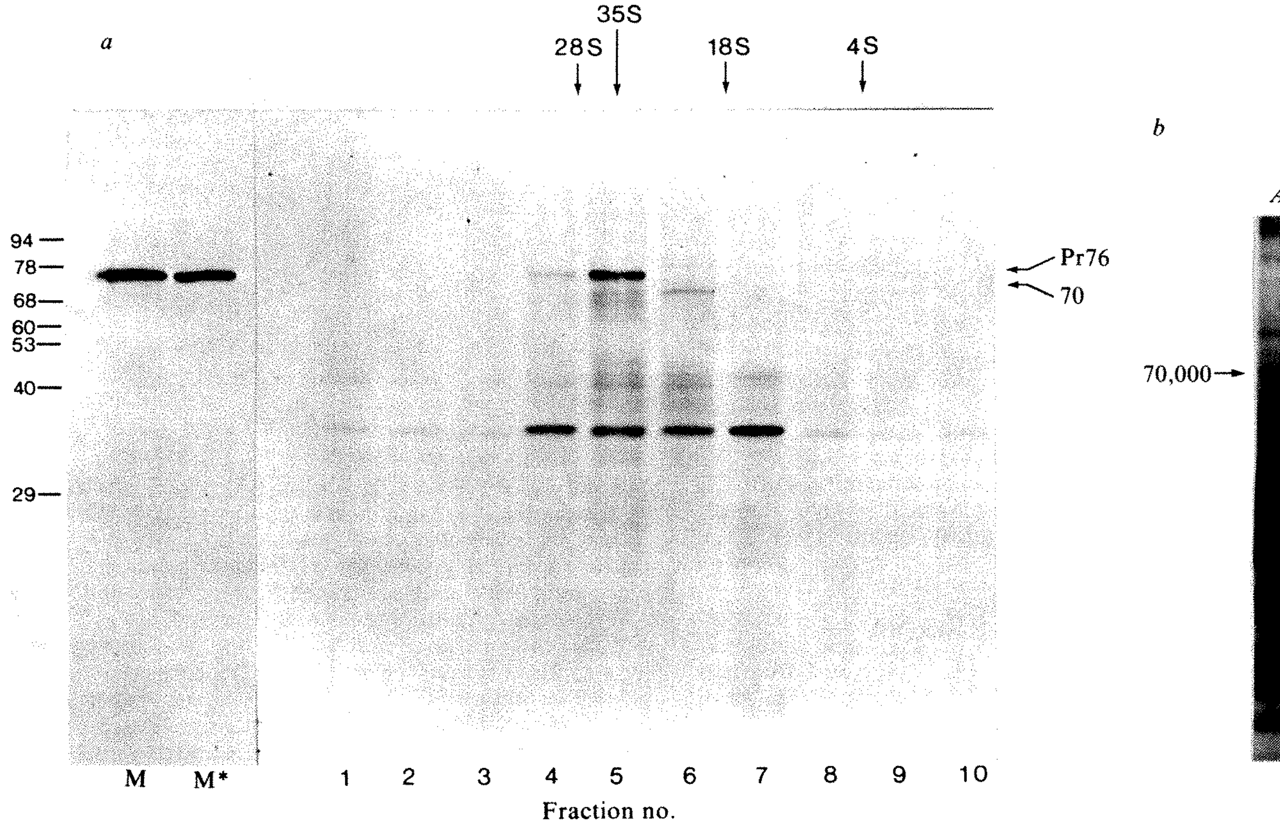
In addition to the gene for the gs antigens, the *gag* gene, RSV virion RNA contains genes for the viral reverse transcriptase, the *pol* gene[9]; the viral envelope proteins, the *env* gene[1,5]; and a gene coding for cell transformation, the *src* gene[1,4,5]. The *src* gene has been positioned at the 3′ end of the 30–40S RNA adjacent to the 3′ poly(A) tail, and the *env* gene to the 5′ side of the *src* gene[1,4,5]. Whether the *src* gene encodes a protein is not yet known.

All the virus-specific RNA present in RSV-infected cells has the same sense as the virion RNA (ref. 10), and two size classes of viral RNA, both of which are present in polyribosomes, have been found in the cytoplasm of RNA tumour virus-infected cells. These are 30–40S virion-like RNA, and a smaller RNA species described by several authors as desimenting between 14S and 27S, the precise size estimate varying with the virus examined and the techniques used[11–15].

These observations have led to various models for RNA tumour virus protein synthesis[6]. At one extreme is the suggestion that 30–40S RNA is the only viral mRNA, and that the viral proteins are synthesised as a single polypeptide precursor which is subsequently cleaved. At the other extreme is a model in which each viral gene is transcribed into a separate mRNA species. The first model would predict that equimolar amounts of each of the viral proteins are synthesised in infected cells, and would consider the sub-genomic viral RNAs and the failure to make anything other than Pr76 *in vitro* in response to 30–40S virion RNA as experimental artefacts. By contrast the second model predicts that since each mRNA may be present in a different amount and translated at a different efficiency, the viral proteins need not be synthesised in equimolar amounts. This model also suggests that virion 30–40S RNA has internal initiation sites and that they are inactive.

To examine the mechanism by which RNA tumour virus proteins are synthesised, we have isolated total poly(A)-containing cytoplasmic mRNA from RSV-infected chick cells. This mRNA has been fractionated on denaturing sucrose gradients, translated in mammalian cell-free systems derived from mouse ascites and L cells. Because infection by RNA tumour viruses does not shut off host-cell metabolism and viral

Fig. 1 *a*, SDS–polyacrylamide gel electrophoresis of viral polypeptides synthesised in the ascites cell-free system in response to fractionated RSV-infected chick embryo fibroblast mRNA and RSV virion RNA. Total poly(A)-containing RNA (mRNA) was isolated from c/o chick embryo fibroblasts infected with cloned nd RSV using methods described previously[6,16]. mRNA (25 μg) and ^{32}P-labelled whole mouse embryo non-poly(A)-containing cytoplasmic RNAs were fractionated separately on two 4.5-ml 2–10% sucrose gradients containing 85% formamide[17]. RNA samples were heated at 37 °C for 5 min in 85% formamide buffer before centrifugation for 16 h at 40,000 r.p.m. in a Beckman SW56 rotor at 25 °C. Gradients were fractionated and 30 μg carrier ascites cell tRNA was added to each fraction of the mRNA gradient. The RNA was precipitated after addition of 0.2 M NaCl and 2.5 vol ethanol, reprecipitated twice, washed once in 95% ethanol and dissolved in water. RSV virion 30–40S RNA was prepared as described[6]. RNA from the gradient fractions 1–10 and virion RNA (M) were translated in the mouse ascites cell-free system[6] and 20 μl samples of the cell-free products immunoprecipitated using the double antibody method[6] with antiserum raised against whole disrupted AMV. The products made in response to virion RNA were also immunoprecipitated with antiserum raised against AMV p12 (M*). The immunoprecipitates were analysed by electrophoresis on a single 15% SDS-polyacrylamide slab gel and the gel prepared for fluorography as described[18]. Because the counts incorporated in response to virion RNA were greater than with virion RNA, the exposure time of tracks M and M* was only 8 h whereas tracks 1–10 were exposed for 2 weeks. The positions of the marker RNAs run in the parallel gradient are indicated. *b*, SDS–polyacrylamide gel electrophoresis following immunoprecipitation with anti-AMV gp85 serum of polypeptides synthesised in the ascites cell-free system in response to 20–25S RNA from RSV-infected chick cells (*A*) and uninfected duck cell (*B*). mRNA was isolated from infected chick embryo fibroblasts and uninfected duck cells and fractionated on 85% formamide sucrose gradients as for *a*. RNA (referred to as 20S–25S RNA) sedimenting between the positions of the 18S and 28S rRNA markers run in a parallel gradient was pooled, precipitated and translated *in vitro*. Samples of the cell-free products were reacted with anti-AMV gp85 serum[19], immunoprecipitated and analysed on 15% SDS–polyacrylamide gels



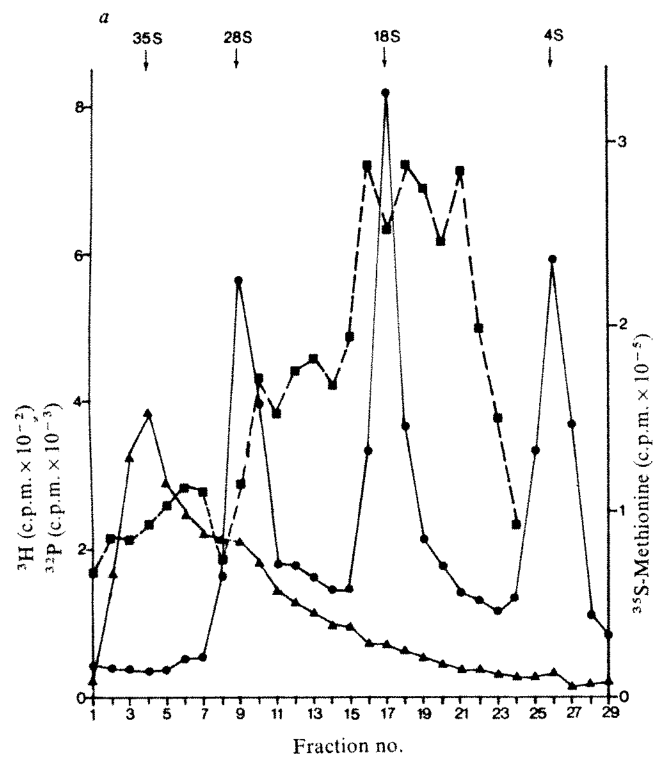


Fig. 2 *a*, Calibration of 5–20% sucrose gradient containing 50% formamide. Total RSV-infected chick embryo fibroblast mRNA (50 μg) was denatured at 37 °C for 5 min in 50% dimethylformamide, 25% dimethylsulphoxide and fractionated on a 50% formamide sucrose gradient[20]. Centrifugation was for 12 h at 35,000 r.p.m. in a Beckman SW40 rotor at 20 °C. ^{32}P-labelled non-poly (A)-containing cytoplasmic RNAs (●) and ^{3}H-labelled RSV 30–40S RNA (▲) were mixed, denatured and fractionated on a parallel gradient. mRNA was recovered from the gradient fractions as described in Fig. 1*a* and translated in an L-cell system supplemented with 50 μg crude rabbit reticulocyte initiation factors[21] per 50 μl incubation. The ^{35}S-methionine incorporated into TCA-insoluble material in a 2-μl sample of the cell-free system in response to RNA from the gradient fractions is, also indicated (■). *b* and *c*, SDS–polyacrylamide gel electrophoresis following immunoprecipitation with anti-AMV p12 serum and anti-AMV gp85 serum of the polypeptides synthesised in the L-cell system in response to RSV-infected chick cell mRNA fractionated on a 5–20% sucrose gradient containing 50% formamide. *b*, Samples (20 μl) of the products made in response to selected fractions of gradient fractionated mRNA (*a*) were reacted with 5 μl normal rabbit serum and incubated at 22 °C for 90 min. The rabbit IgG was removed by binding to protein A present on the surface of *Staphylococcus aureus*[22], followed by centrifugation. This procedure was designed to reduce the background of nonspecific precipitation. The supernatant was reacted with 5 μl rabbit anti-AMV p12 antiserum and the immunoprecipitates collected using the double antibody method[6]. An incubation containing no added RNA (b), and one containing virion 30–40S RNA (M) were treated in the same way. All the samples were run on the same 15% SDS–polyacrylamide gel and the gel was subjected to fluorography. Because of the differences in counts, track M was exposed for only 24 h whereas the remainder of the gel was exposed for 3 weeks. *c*, As for *b* except that immunoprecipitation was with anti-AMV gp85 serum and a different selection of fractions were translated.

mRNA constitutes only a small fraction of total mRNA activity, the viral proteins made *in vitro* were isolated by immunoprecipitation using various antisera raised against avian RNA tumour virus proteins.

Fractionation of infected cell mRNA

Poly(A)-containing cytoplasmic RNA was isolated from c/o chick embryo fibroblasts transformed with non-defective Prague-C RNA, from uninfected chick cells, and from duck fibroblasts (which do not contain detectable endogenous viral sequences). These mRNAs were fractionated on 2–10% sucrose gradients containing 85% formamide. ^{32}P-labelled 18S and 28S rRNA and ^{3}H-labelled RSV virion 30–40S RNA were sedimented as markers in a parallel gradient. RNA from each of the gradient fractions was recovered and translated in the ascites cell-free system. The cell-free products were immunoprecipitated with antiserum raised against detergent-disrupted AMV, which contains antibodies against both the gs antigens and the envelope glycoproteins, and the immunoprecipitates were analysed by electrophoresis on SDS–polyacrylamide slab gels. RSV virion 30–40S RNA was translated, immunoprecipitated and electrophoresed together with the products made in response to fractionated mRNA.

Figure 1*a* shows that only one polypeptide is immunoprecipitated from cell-free incubations containing added virion

30–40S RNA, using either anti-AMV or anti-p12 sera. We have previously identified this as Pr76, the precursor to the viral structural proteins[6]. Because less radioactivity is present in the immunoprecipitates of material made in response to the fractionated mRNA, this region of the gel was autoradiographed for longer. This reveals that a background of proteins (notably actin) which is present in the material immunoprecipitated from all fractions, is also immunoprecipitated by control serum, and uninfected duck cell mRNA products. In addition to the background, there is a polypeptide which comigrates with marker Pr76 and is synthesised from an mRNA activity from RSV-infected cells which sediments slightly slower than the 28S RNA marker (Fig. 1*a*). On 85% formamide sucrose gradients, virion 30–40S RNA also sediments slower than 28S RNA.

A further polypeptide which we estimate to have an apparent molecular weight of 70,000 is immunoprecipitated by antiserum to disrupted virions from the products made in response to mRNA from infected cells. The mRNA coding for the 70,000 polypeptide sediments slower than the mRNA coding for putative Pr76. Virion RNA does not code for the 70,000 protein (Fig. 1*a* track M).

The 70,000 molecular weight polypeptide synthesised by RSV-infected cell mRNA is not immunoprecipitated by control rabbit serum, nor is it detected when uninfected chick or duck cell mRNA are translated and immunoprecipitated (data not shown). To characterise the 70,000 protein further we have used antisera raised against purified viral components. The 70,000-MW polypeptide was not immunoprecipitated by antiserum raised specifically against the group-specific antigen, P12, which precipitates Pr76 made *in vitro*[6]. Antiserum raised specifically against the major viral glycoprotein gp85, however, immunoprecipitated the 70,000 protein from the translation products of total unfractionated infected cell mRNA and of the 20–25S fraction. Figure 1*b* shows the immunoprecipitates obtained with anti-gp85 from the products made in response to 20–25S RNA from infected chick cells and uninfected duck cells. Although there is a high background it is clear that the 70,000 protein is only present in the product made by infected cell mRNA. The results of the immunoprecipitation experiments indicate that the 70,000 polypeptide may be a virus-specific molecule, and if so, that it may be related to the envelope glycoprotein gp85.

The experiment shown in Fig. 1 used 85% formamide sucrose gradients because they are reported to be highly denaturing[17] and we have previously found such conditions to be necessary to reduce mRNA–mRNA interactions to a minimum[16]. These gradients, however, do suffer the disadvantage that mRNAs larger than about 18S do not sediment at their true rate. Indeed, as already mentioned, ^{3}H-labelled 30–40S virion RNA sediments slower than 28S rRNA in these conditions. Thus, although the results presented in Fig. 1 do not allow us to assign accurate sedimentation constants to the different RNA fractions, they do indicate that the mRNA coding for putative Pr76 is different and separable from that coding for the 70,000-dalton protein.

To achieve a greater separation of the two mRNAs from RSV-infected cells, and a more accurate estimate of their size, we repeated the experiment but in this case used 50% formamide sucrose gradients and collected more fractions. To identify the products we translated RNA from selected fractions in an L-cell S30 and immunoprecipitated the products with the two specific antisera, against the purified gs antigen P12 and against purified viral glycoprotein gp85, mentioned above. To reduce the background of immunoprecipitated material which we found to be higher when using the monospecific antisera (Fig. 1*b*) we introduced a pre-immunoprecipitation step using control serum as described in the figure legend.

Figure 2*a* shows the position of 18S and 28S rRNA and 30–40S virion RNA sedimented on a 5–20% sucrose gradient containing 50% formamide, and also the ^{35}S-methionine incorporation into TCA-insoluble material when infected cell mRNA was fractionated on a parallel gradient and translated in the L-cell system. Figure 2*b* shows that a polypeptide, which comigrates on SDS–polyacrylamide gel electrophoresis with marker Pr76, is immunoprecipitated by anti-P12 serum from the products made in respones to an mRNA activity which cosediments with virion 30–40S RNA. Pr76 cannot be detected in the products made from mRNA sedimenting slower than about 28S.

When the translation products of infected cell mRNA in the L-cell system are subjected to immunoprecipitation with antiserum raised against AMV gp85, Pr76 is not detected in the immunoprecipitates (Fig. 2*c*). The 70,000-MW polypeptide can be seen, however, and is translated from an mRNA activity well separated from that coding for Pr76, sedimenting between about 20 and 28S. In spite of the pre-immunoprecipitation step, a considerable background still remains in the immunoprecipitates with anti-gp85 serum (Fig. 2*c*). Nevertheless immunoprecipitation of the 70,000 protein seems to be specific since when uninfected duck cell mRNA was translated and immunoprecipitated with the anti-gp85 serum, the background was still seen but the 70,000 protein was absent (for example see Fig. 1*b*); further, the 70,000 protein was not immunoprecipitated by the anti-P12 serum (Fig. 2*b*).

A model for the translation of viral RNA

The data presented here suggest that in chick cells productively infected with non-defective RSV, the only RNA species which can actively direct the synthesis of the gs antigen precursor Pr76 is a polyadenylated RNA of the same size as virion 30–40S RNA. Whether the 30–40S cellular RNA species which codes *in vitro* for the synthesis of Pr76 is identical to virion 30–40S RNA, or whether there are two forms of viral RNA of this size, one of which is translated and the other is encapsidated, is unknown. Although we have not yet measured the amount of viral RNA present in the infected-cell mRNA, estimates based on previously published reports[11,23–27] indicate that there is no striking difference in the translational efficiency of cellular 30–40S RNA and virion 30–40S RNA in coding for Pr76. Some of the high molecular weight viral RNA from infected cells may originate from nucleocapsid where *in vivo* it is probably not available for translation. If all the 30–40S RNA were encapsidated, however, and there was a virus-specific mRNA smaller than 30–40S RNA directing the synthesis of Pr76 in these cells, we should have detected it.

In addition to the Pr76 viral polypeptide, a 70,000-molecular weight polypeptide has been detected in the translation products of mRNA from infected cells. The suggestion that this polypeptide is a viral-specific product and possible envelope glycoprotein precursor is based on the finding that it is immunoprecipitated by anti-disrupted virus serum (Fig. 1*a*) and by anti-gp85 serum (Fig. 2*c*), and not by control or anti-P12 serum (Fig. 2*b*). Further, it cannot be detected in the translation products of uninfected cell mRNA (Fig. 1*b*).

We are not aware of any example of a eukaryotic protein that, following synthesis *in vitro*, is extensively glycosylated. It is therefore not surprising that the protein made *in vitro* does not migrate with the reported mobility of viral gp85. Our results are consistent, however, with the observation that when RSV-infected cells are pulse labelled and cell lysates subjected to immunoprecipitation with anti-gp85 serum, an incompletely or non-glycosylated precursor to gp85 is detected (P70) and this has an apparent molecular weight on SDS–polyacrylamide gels of 70,000 (ref. 28). Since the antiserum used was from the same laboratory as that used in our study and the apparent molecular weights of the two proteins are similar it seems possible that our 70,000 protein is the non-glycosylated polypeptide moiety of gp85. It must be emphasised, however, that the identification of the 70,000-molecular weight polypeptide translated from infected cell mRNA is based solely on immunoprecipitation. Rigorous identification of the polypeptide must await the development of new methods which will enable us to purify sufficient virus-specific cytoplasmic mRNA to give

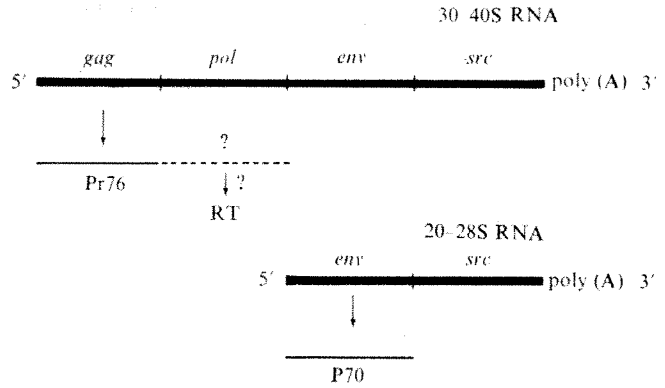

Fig. 3 Possible model for the synthesis of virion RNA proteins.

cell-free products which can be analysed by tryptic peptide fingerprinting.

The results presented here suggest that the two size classes of viral RNA that have been detected in the polysomes of infected cells by several groups both actively direct the synthesis of viral proteins. The finding that the mRNA activity sedimenting between 20–28S codes *in vitro* for a 70,000 polypeptide, but that virion RNA or virion-sized mRNA from infected cells do not code for this protein suggests that the two mRNAs have different coding activities. Possibly the 20–28S RNA represents the 3′ half of virion 30–40S RNA and the corresponding internal initiation sites for protein synthesis present in virion RNA is inactive (see Fig. 3). Such a model is similar to those already presented for the synthesis of Semliki forest virus structural proteins[29], polyoma virus capsid proteins[16], and several plant virus capsid proteins. Bloemendal and colleagues[34,35] have reported similar experiments to those described here and have shown that different species of viral mRNA from cells infected with murine leukaemia virus (MuLV) have different coding activities. These experiments are also consistent with the model shown in Fig. 3.

How the *pol* gene is translated is still unclear. Arlinghaus *et al.*[30] have reported that a precursor to the viral proteins of molecular weight 200,000 is present in MuLV-infected cells and that this includes the structural proteins and possibly the reverse transcriptase. Kerr *et al.*[31] have synthesised a 180,000-molecular weight polypeptide *in vitro* in response to MuLV 30–40S virion RNA. This protein includes the tryptic peptides of the structural proteins, but no further components have yet been identified. It is likely that the high molecular weight protein found in the murine system is the product of read-through from the *gag* gene into the *pol* gene, but that this readthrough does not occur in every case. Such a model would be similar to that for the synthesis of bacteriophage Qβ coat protein and its readthrough product, the A_1 protein[32] and for the synthesis of Mengo virus proteins late in infection[33].

While this manuscript was in preparation, Mueller-Lantzsch and Fan[36] reported that the only viral RNA species present in polysomes immunoprecipitated by anti-MuLV p30 serum from total infected cell polysomes has a sedimentation rate of 30–35S.

We thank Dr D. Bolognesi for gifts of anti AMV gp85 and anti-AMV p12 sera and Dr G. S. Martin for a gift of cloned nd PrC-RSV. We also thank Dr R. Kamen for ^{32}P-labelled rRNA, De Y. Ito for *S. aureus*, and Dr H. Dahl for reticulocyte initiation factors.

Note added in proof: Since this manuscript was submitted other authors have reported that RSV subgenomic mRNAs from infected cells direct the synthesis of the viral glycoprotein when injected into chick cells[37] and oocytes[38].

Cyg X-3: γ rays from a magnetic accretion disk

THE recent observation[1] of ~ 100-MeV γ rays from Cygnus X-3, which have a comparable luminosity to the X-ray emission and which vary in phase with the 4.8-h period displayed by the X-ray and infrared emission, has been taken[2, 3] as support for the suggestion[4] that the X-ray emission is produced by a very young pulsar in a short period binary system. In this letter, we show that the observed γ-ray luminosity can be produced by an accretion disk around a non-magnetic neutron star or low-mass black hole, in a magnetised corona which accelerates relativistic electrons that decay by inverse Compton losses modified through the photon–photon and pair-annihilation processes.

The dominant dissipative mechanism in the disk is assumed to be due to magnetic fields. The shearing motion of the disk increases the azimuthal field strength in the disk until the magnetic pressure is comparable with thermal (or radiation) pressures inside the disk. We then expect the field lines to bow apart from the disk to form a magnetic corona above the disk as described by Parker[5]. This process may also turn sufficient of the azimuthal field into poloidal directions so that a dynamo mechanism operates. Since the Alfvén speed in the corona exceeds that in the disk (where most of the matter resides) and since the lengthscales associated with field reversals should be comparable in both regions, we expect most of the dissipation of magnetic energy (through field annihilation and particle acceleration) to take place in the corona and not in the disk itself. There is a self-consistent equilibrium situation in which the disk is kept at X-ray temperatures producing photons with energy $E_x \sim 10$ keV. The relativistic electrons (energy $= \gamma m_e c^2$) generated by the field annihilation, lose energy predominantly by inverse Compton losses by upscattering the X-ray photons to γ-ray energies. Taking an X-ray luminosity[6] of $L_x \sim 5 \times 10^{37}$ erg s^{-1} to be coming from the inner part of a disk, a region of radius $R \sim 3 \times 10^6$ cm, we find that the energy density of X-ray photons is $\varepsilon_x \sim 3 \times 10^{13}$ erg cm^{-3} with corresponding X-ray photon number density $n_x \sim 2 \times 10^{21}$ cm^{-3}. For these parameters, and for $\gamma_2 = 10^{-2} \gamma \leqslant 1$, the energy loss timescale for an electron to inverse Compton scattering is $t_{ic} \sim 10^{-8} \gamma_2^{-1}$ and the corresponding radiation path length is $\lambda_{ic} \sim c t_{ic} \sim 3 \times 10^2 \ \gamma_2^{-1} \ll R$ (for standard disk densities[7], energy loss in the rough nuclear collisions is negligible). For synchrotron losses to be unimportant the magnetic field strength must satisfy $B^2/8\pi \leqslant \varepsilon_x$, that is $B \ll 3 \times 10^7$ G. The equipartition field in a standard accretion disk[7] at the above radius is $\leqslant 4 \times 10^7$ G. We may expect the magnetic field to be somewhat less in the corona and, hence, take $B = 10^7$ G.

To produce the required γ-ray photons with energy $E_\gamma \sim 100$ MeV we require $\gamma^2 \sim E_\gamma/E_x$, or $\gamma_2 \sim 1$. When $\gamma > m_e c^2/E_x \sim 50$, the Klein–Nishina cross section is relevant and the energy of the γ ray produced in a collision is $E_\gamma \sim \gamma m_e c^2$. The energy loss timescale for an electron with $\gamma_2 \gg 1$ is $t_{ic}^* \sim t_{ic}\gamma_2^2$.

Assuming that magnetic field reconnection takes place at a velocity $\sim 0.1 \ V_A$, where V_A is the Alfvén velocity in the corona[8], we may estimate the induced electric field to be $E \sim (0.1 V_A/C)B$. The particle density in the corona is sufficiently low that we may take $V_A \sim c$ and estimate $E \sim 10^6$ units. If the particle acceleration occurs over a length, λ cm, we have that $\gamma_2 \sim 10^{-3} eE\lambda/(m_e c^2) \sim 5\lambda$ (ref. 9). For self-consistency we demand that $\lambda \leqslant \lambda_{ic}$ and hence that $\gamma_2 \leqslant 0$. It seems possible, therefore, that the initial photons produced have energies $\gg 100$ MeV. We note, however, that photons with energies $E_\gamma \gtrsim E_s \sim 4(m_e c^2)^2/E_x \sim 100$ MeV) can undergo photon–photon interactions[10], with cross section $\sim \sigma_T$, the Thomson cross section, to produce electron–positron pairs with $\gamma_2 \geqslant 1$. The optical depth of such γ rays in our region is $\tau_\gamma \sim n_x \sigma_T R \sim 10^3$. The pairs so produced then lose their energy by inverse Compton interactions (on a timescale $\sim t_{ic}^* \sim \gamma_2/(n_x \sigma_T c)$ at a rate faster than they annihilate (on a timescale $\sim 10^2 \gamma_2/n_\pm \sigma_T c$ where $n_\pm$ is the electron–positron number density[11]). (We shall show that $n_\pm \sim n_\gamma$ and since $L_x \sim L_\gamma$ then $n_x \sim 10^4 n_\gamma$). In this way, all photons are degraded to energies $\sim E_s$ before escaping from the corona. This also implies that the rate of formation of electron–positron pairs is comparable to the rate of production of ~ 100-MeV photons. The timescale for escape of photons is $t_p \sim R/c \sim 10^{-4}$ s whereas the annihilation timescale (now with $\gamma \sim 1$) is $t_\pm \sim 1/(n_\pm \sigma_T c)$. If n_γ is the number density of γ-ray photons with $E_\gamma \sim 100$ MeV, therefore, in a steady state $n_\pm/n_\gamma \sim t_\pm/\mathrm{t}_p$ and hence $n^2_\pm \sim n_\gamma/(R\sigma_T)$. Assuming a γ-ray luminosity $L_\gamma \sim 10^{37}$ erg s^{-1} we find that $n_\gamma \sim 10^{17}$ cm^{-3} and hence that $n_\pm \sim 2 \times 10^{17}$ cm^{-3}. The annihilation of the electron–positron pairs gives rise to a line in the region of 500 keV which contains a photon flux comparable with that in γ rays, that is a luminosity $L_\pm \sim (m_e c^2/E_\gamma) L_\gamma \sim 10^{35}$ erg s^{-1}.

Once the γ rays have been sufficiently degraded they can escape from the coronal region. About a half of them can escape to infinity but the rest enter the accretion disk itself. From the standard disk model we find the surface density of the disk to be ~ 5 g cm^{-3}, so that the γ rays are absorbed by the disk. They heat the disk to X-ray temperatures (thus ensuring the self-consistency of our assumption). In this model we find, therefore, that the rough equality of L_x and L_δ arises naturally.

We can further examine why this process produces γ rays for a disk model of Cyg X-3, but may not for other sources in which disks may be present. From the standard disk model, the magnetic field strength in the disk in the neighbourhood of the central regions is $\sim 10^8 (M/M_\odot)^{-\frac{1}{2}} (R/3R_s)^{-\frac{3}{4}}$ G (where M is the mass of the central object and $R_s = 2GMc^{-2}$) independent of the accretion rate. If, therefore, ε_x falls much below the value we find that for Cyg X-3 the dominant loss process for the relativistic particles is synchrotron radiation which produces photons in the X-ray range. Thus, if the luminosity of the X-ray source is too low, or if the area of the emitting region is too high (for example, for a $10 M_\odot$ black hole in Cyg X-1), the energy is radiated almost entirely as X rays, some thermally from the disk and some non-thermally as synchrotron radiation from the corona.

An irregular time variability, or the occasional disappearance of the γ-ray emission of Cyg X-3, could occur if $\dot{M}$ (and consequently ε_x) drops below the value required for inverse Compton losses to dominate over synchrotron, or if $\dot{M}$ increases to a value where the total luminosity approaches the Eddington value and disk symmetry is destroyed. In both cases, one could expect the γ-ray emission to dissappear while the X-ray emission remains, albeit with somewhat different spectral characteristics.

The 4.8-h variation in the observed γ-ray flux can be produced in the same manner as the X-ray variation, using the model of Pringle[12]. In this model, the X-ray variation is produced by the variation with binary phase of the electron scattering optical depth to the X-ray source through a dense wind emanating from the companion star. We expect the γ-ray variation to be more pronounced, since the X-ray variability is smoothed somewhat by the backscatting of X-ray photons. On the other hand, backscattered γ-ray photons are degraded by Compton recoil.

Are striations on Phobos evidence for tidal stress?

VIKING orbiter photographs of Phobos, the inner satellite of Mars, reveal a curious series of striations or grooves over much of the surface[1]. These features cross over large eroded craters but are in turn interrupted by very small well defined craters, which indicate an origin substantially later than the time of formation of the satellite itself when the large scale cratering presumably occurred. The grooves have no obvious connection with the 'crater chains' also seen in Phobos, and their nearly parallel spacing seems to rule out an origin due to primary or secondary impacts. We suggest that some of these features are related to readjustment of the satellite's figure with increasing tidal stress as the orbit evolves inwards under the action of tidal friction.

The present rate of orbital decay[2] suggests that Phobos's original orbit had a radius $a \sim 5R$ (R is martian radius) and that the present orbit, at $2.76R$, will decay to the martian surface (unless the satellite breaks up first) within $\sim 10^8$ yr. The tidal (plus centrifugal) stress, $\sigma \propto a^{-3}$, has already increased by a factor of ~6 since the origin of Phobos.

The magnitude of σ is now of order $\Omega^2 \rho r^2 \approx 10^5$ dyn cm^{-2}, where Ω is the angular velocity, ρ the density, and r the radius of the satellite. If Phobos has a deep regolith layer of material similar to lunar dust, one might expect a material strength[3] near the surface as low as 10^3–10^4 dyn cm^{-2}. Thus even if the interior were perfectly rigid, tensile stress fields in the weakly cohesive surface regolith might give rise to patterns of parallel cracks. With the addition of a mechanism for the partial readjustment in the figure of Phobos under tidal stress, the surface cracks could then be widened into the observed series of grooves or graben.

For example, slow viscous creep due to subsurface permafrost could allow tensile cracks to widen. Spacecraft perturbations indicate a density[4] for Phobos of about 2 g cm^{-3}. This low value, together with the satellite's observed photometric and polarimetric properties[5], suggests a carbonaceous chondritic and hence water-rich composition, so that permafrost is not unreasonable. Shock waves due to impacting bodies might also enhance the readjustment of the figure.

If Phobos is homogeneous, its low mean density places it inside the classical Roche limit for the gravitational instability of a fluid body (ref. 6). Therefore, either the satellite has a denser core (we thank Dr S. Dermott for clarifying this point) or, if homogeneous, it possesses sufficient rigidity to prevent full readjustment on the timescale of orbital evolution ($\sim 10^8$ yr).

One very prominent series of grooves is arranged nearly concentrically around the tidal equator (normal to the satellite's long axis), which orientation is to be expected from tidal stress theory[7]. Shear failure at moderate depths, where the principal stresses are all compressive, might give rise in addition to transcurrent faults, and there is perhaps an indication of this in some of the Phobos pictures showing sets of obliquely intersecting striations.

If the width of the grooves is in fact due to tidal readjustments of the figure of Phobos, then the older craters should be systematically deformed from their initial nearly circular shapes. Craters near the tidal equator would be elongated parallel to the satellite's long axis. A similar suggestion was made by Öpik[8] with respect to the Moon, but the effect for Phobos would be more pronounced.

Striations and other deformations due to tidal stress should be nearly absent on Deimos. The outer satellite has always been beyond the synchronous distance ($6.0R$) and at present ($a = 6.92R$) has a tidal stress about 60 times weaker than that for Phobos.

An investigation is being made of the possible role of subsurface ice in producing the detailed morphology and distribution of tidal stress features on Phobos.

We thank S. Dermott, T. Duxbury, T. Gold, and J. Veverka for discussions. This work was supported by NASA Planetology Program Grant NGR 33-010-220 (at Cornell) and by NASA Contract NAS 7-100 (at JPL).

Geomagnetic storms and electric fields in the equatorial ionosphere

LARGE variations of the geomagnetic field observed at ground level during a geomagnetic storm are generally attributed to various magnetospheric changes following the arrival of the solar plasma ejected during the solar flare. Using the direct measurements of equatorial electric field during a geomagnetic storm, it is shown here that the large decrease in the field observed near the dip equator is due to the reversal of the equatorial electrojet current. This event is caused by the imposition of an additional westward electric field on the equatorial ionosphere which was originated by the interaction of solar wind with the interplanetary magnetic field.

A standard type of geomagnetic storm consists of a sudden increase of the horizontal (H) field at ground level within a few minutes at all world stations (called storm sudden commencement—SSC) followed by the initial phase (IP) for a few hours when the H field is above normal. The main phase (MP) of the storm is supposed to start when the H field decreases below the pre-SSC level and ends when **H** reaches the minimum value. The recovery phase follows the main phase and may last one or two days. The history of a particular storm can be identified better by the temporal changes of the equatorial $\mathbf{D}_{st}$(H) values rather than from temporal variation of **H** at a particular station.

The first explanation of the various effects of the geomagnetic storm was by Chapman and Ferraro[1] with the concept of neutral ionisation moving from the Sun through the geomagnetic cavity. The SSC was explained in terms of an enhancement of the electric current induced on the surface of the cavity by the ion stream, and the MP was caused by a ring current surrounding the Earth. Dessler[2] suggested the SSC to be produced by hydromagnetic shock wave generated at the frontal surface. Rastogi and Trivedi[3] showed that the amplitude of SSC(H) at low latitudes is greatly enhanced in a way similar to the enhancement of Δ**H** within the equatorial electrojet region, and thus the SSC near the dip equator was suggested to have a significant contribution due to ionospheric currents. Akasofu and Chapman[4] have shown that polar geomagnetic storm can greatly enhance the equatorial electrojet current. Rastogi[5] has shown that the changes of H field during SSC at a low-latitude station are due to the imposition of an additional electric field over the equatorial ionosphere causing additional SSC-associated electrojet currents. Onwumechilli *et al.*[6] have shown that during moderately disturbed periods, the polar *Sq* variation ($S_q{}^P$) is enhanced and the electric field associated with it affects the equatorial electrojet by suppressing it. Further, the substorm-associated electric field driving the eastward current in the auroral zone causes an enhancement of the equatorial electrojet. An experimental verification of the coupling between equatorial and auroral electric fields has been recently reported by Kelley *et al.*[7], when the eastward electric field measured at the equatorial station Jicamarca by the Doppler shift of VHF scatter is very well correlated with the westward electric field at auroral station College Alaska measured by balloon-borne detectors.

Woodman[8] has recently described the vertical as well as eastward F-region drifts at Jicamarca. At these regions of the ionosphere, these drift velocities are a direct measurement of the electric field in a direction orthogonal to drift and to the direction of the magnetic field. Thus a technique of continuous monitoring of ionospheric electric fields over

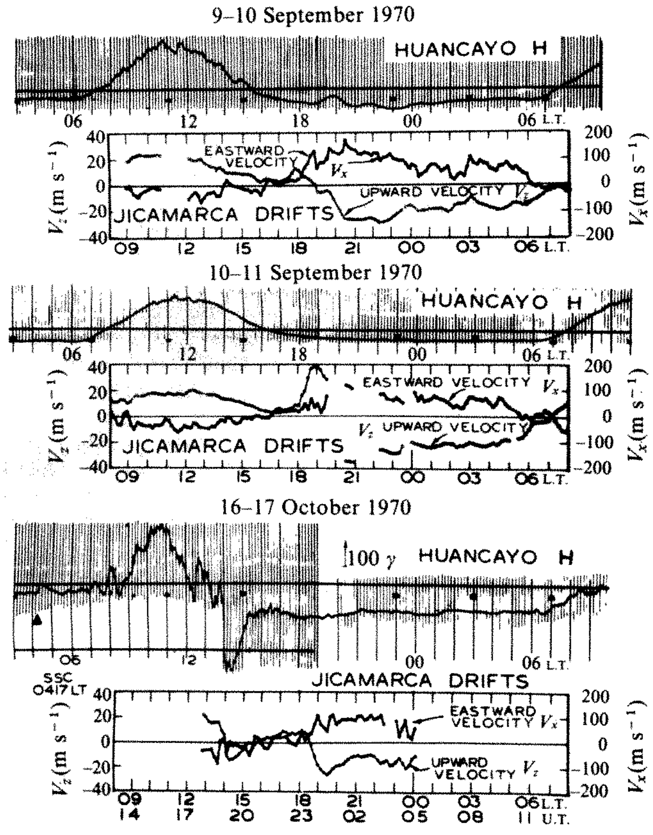

Fig. 1 Comparison of the F region upward and eastward drift velocities at Jicamarca with the magnetograms at Huancayo.

the dip equator has been provided through VHF scatter radar. The data were presented for three days 9–10 September 1970, 10–11 September 1970 and 16–17 October 1970. The first two days, 9–10 and 10–11 September 1970 were geomagnetically very quiet while 16–17 October 1970 was one of the five disturbed days of the month. A sudden commencement type of geomagnetic storm had occurred on 16 October 1970 at 0917 UT (0417 LT). In Fig. 1, these data of upward velocity (V_z) and eastward velocity (V_x) are compared with the corresponding magnetogram of Huancayo.

In Fig. 1, the H field at Huancayo varies very smoothly on 9–10 and 10–11 September 1970. In the evening of 10 September 1970, the vertical drift (or eastward electric field) had a very prominent peak around 1900 LT before the usual evening reversal of its direction. No effect of this sudden increase of the electric field could be seen in the magnetogram because the E region plasma had greatly decreased by 1900 LT and so no significant currents could be produced due to the increase of the electric fielt. On 9–10 September 1970, the evening peak of the vertical drift was absent. The magnetogram for 16–17 October 1970 shows a sudden increase of the H field at 0417 LT due to sudden start of geomagnetic storm. There is a remarkably large and sudden decrease of the H field between 1400 LT and 1530 LT. The vertical drift at Jicamarca shows a large excursion such that the drift was downward between 1400 LT and 1540 LT. Thus, this large decrease of H field near the dip equator during the geomagnetic storm period seems to be due to electric currents in the electrojet region itself due to imposition of a reversed electric field. As described by Woodman[8], the eastward dift shows consistent behaviour from day to day even during a magnetic disturbed day. The variations of the geomagnetic field are further studied in detail in Fig. 2 which depicts the variations of the H field at Huancayo, Fuquene and Huancayo minus Fuquene in American zone and at Kodaikanal, Alibig and Kodaikanal minus Alibig in Indian zone. The corresponding variations of the $\mathbf{D}_{st}(H)$ values, the auroral electrojet (AE) index, interplanetary magnetic field magnitude (**B**) and the latitude (θ) are also shown. The latitude $\theta = -90^\circ$ shows the IMF vector entirely southward while $\theta = +90^\circ$ shows IMF vector entirely northward.

It is seen that the $\mathbf{D}_{st}$ became negative at 1130 UT which signifies the starting of the main phase of the storm. This tallies very well with the variations of **H** at Kodaikanal and at Alibag. The difference fields Kodaikanal minus Alibag is very low during the entire period suggesting that most of the storm effects at Kodaikanal were of magnetospheric origin, and this is consistent with the fact that the storm period was local night for these stations. The onset of MPO does not seem to have affected the Huancayo **H** values which shows a peak before noon. The disturbance field was thus too small to cancel the equatorial electrojet field at Huancayo. At 1400 LT (1900 UT) the H field at Huancayo shows a sharp decrease but no change was noticeable at Fuquene. Thus, this $\Delta\mathbf{H}$ at Huancayo seems to be entirely due to change in the equatorial electrojet current and not due to any changes in the magnetospheric currents. It is remarkable that the Huancayo

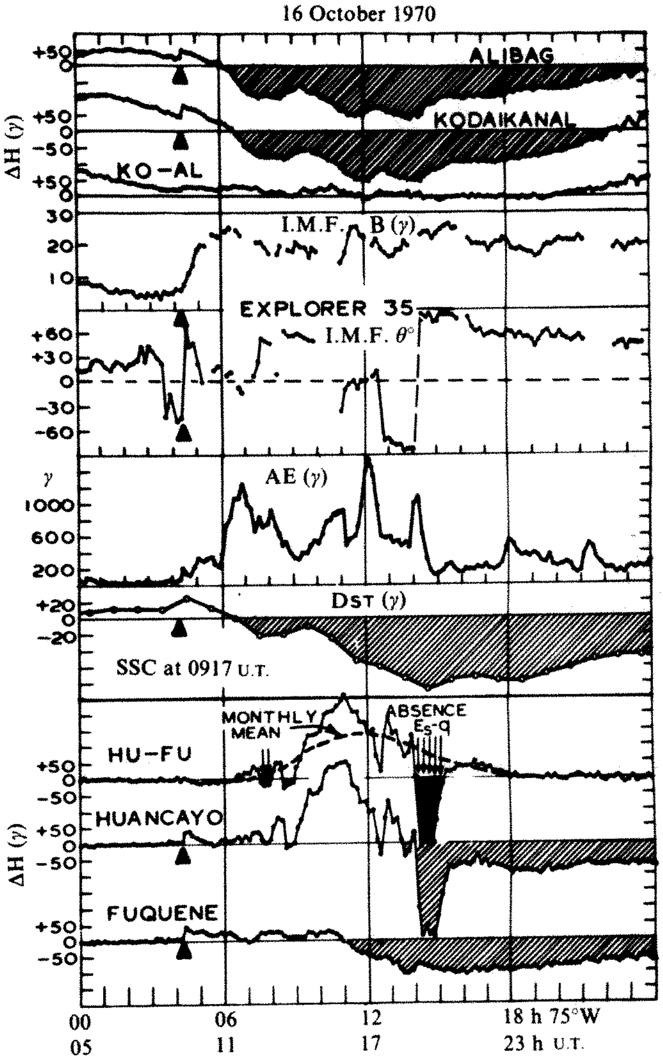

Fig. 2 Comparison of the magnetic field variations at low latitudes during a geomagnetic storm with the auroral index and the interplanetary magnetic field parameters.

ionograms showed absence of the *q* type of E_s layer confirming that the horizontal electric field at the E region over Huancayo between 1400 and 1530 LT was reversed to westward. Examining the AE index, one notices increase of the index around 0700 LT, 1200 LT and 1400 LT. The intense activity of auroral electrojet at 0700 LT did produce some decrease of the **H** at Huancayo between 0800 and 0900 LT. The large increase of AE around 1200 LT decreased the H field around 1230 LT. The most prominent decrease of H field at 1400 LT is associated with the sudden increase of the auroral index at 1400 LT.

Examining the changes of IMF parameters one notices that after the sudden start the magnitude (**B**) had increased from its about usual value of 5 γ to above 20 γ and remained high for the rest of the day. This high value of IMF made the interaction of the field with the solar wind most effective. The direction of the field perpendicular to the ecliptic (θ) shows sudden change at SC and later at 1200 LT. The most remarkable change occurred at 1400 LT when the field flipped from almost the southward to the northward direction. The field remained northward for the rest of the day. Thus the component of the IMF perpendicular to the ecliptic, $\mathbf{B}_z$, component interacting with the solar wind plasma moving practically along the Sun–Earth direction produces *a* $V_x\mathbf{B}_z$ field along the east–west direction. A sudden reversal from southward to northward direction would present a strong westward electric field on the dayside of the Earth. The large increase of the AE index and the reversal of the equatorial electrojet at 1400 LT are ascribed to the sudden flipping of the $\mathbf{B}_z$ component of the interplanetary magnetic field.

Similar effects of the sudden reversals of the $\mathbf{B}_z$ component on the equatorial ionosphere have been previously described by Rastogi and Patel[9]. Similar effects seen during geomagnetic storms show, for the first time, that the observed magnetic field changes near the magnetic equator during geomagnetic storms have significant contribution due to the changes of the electrojet currents in the ionosphere through the modulation of the east–west electric field in the ionosphere. These changes at the equator are suggested to be of the solar wind origin manifested through the changes of the auroral electrojet currents.

Bimodal distribution of creep event amplitudes on the San Andreas fault, California

EPISODIC fault creep at several instrument sites along the San Andreas and associated faults in central California consists of a few small and large slip events per year generally superimposed on a background of gradual yielding at low rates[1–3]. Most of the events are aseismic, but a few minor displacement steps have occured in association with local earthquakes[1,2]. After removal of earthquake steps, event lists for several sites include significant numbers of small events about an order or magnitude below the typical 1–4-mm amplitude range for large events[1,3]. Recent experimental rock-deformation results demonstrate that under biaxial loading some rocks show episodic slip on pre-cut surfaces[9,10]. It is not yet clear how the laboratory and field observations are related, but the data presented here indicate that episodic fault creep in nature may be more complex than previously realised. In light of the laboratory results, it is more important than ever to consider all the details of the field data concerning fault creep.

The performance of various types of non-wire creepmeters is usually adequate for monitoring large creep events, but these higher friction instruments generally produce incomplete or unreliable results at the level of sensitivity necessary for study of small events[2,12]. Several invar wire creepmeters with low friction and displacement resolution of 0.05 mm or better have, however, been operated nearly continuously within the network since 1972 (ref. 1). At sites characterised by episodic

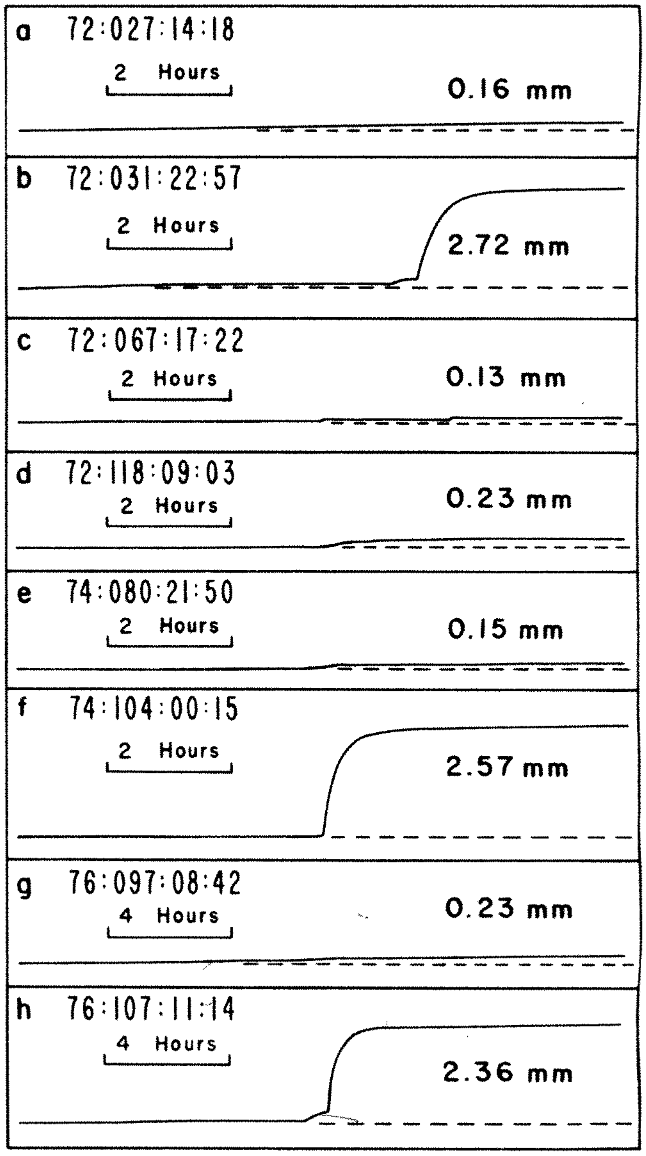

Fig. 1 Tracings from on-site strip-chart records produced at XMR1 creepmeter (36°35.6′N, 121°11.2′W). Onset times for each event are given by yr, Julian d, h and min (GMT). Trace *f* shows a typical large creep event with 80% of the slip occurring in about 1 h. Traces *b* and *h* show similar events except that both are preceded by small precursory movements of about 0.2–0.3 mm. Trace d shows an isolated small event with a rise time similar to that for most large events. Although trace *d* represents the majority of small events, a few with shorter rise times (traces *c* and *e*) and with rise times of several hours (traces *a* and *g*) also occur.

creep, the low-friction wire creepmeters confirm the general pattern of large isolated creep events recorded on the other instruments, but show additional interesting detail concerning the nature of small events.

Records combined from one wire (XMR1)[1,3] and four rod-type creepmeters (MRC, MRB, MRR, MRW)[2,3] clustered along the San Andreas fault trace on Melendy Ranch (36°35′N, 121°11′W) show that most of the large events have rise times of the order of 1 h. These events often propagate at several hundred metres per hour along the entire 1.2-km fault segment covered by the five-station network[1-5,7]. From these and similar observations elsewhere it is clear that large creep events typically involve fault lengths on the order of a kilometre in episodic aseismic slip of a few millimetres amplitude[6,8]. Whatever the actual depth of creep events, it is also clear from consideration of source length alone that considerable volumes of material are involved in the process.

One of the most complete samples of creep event activity is contained in the 1972–76 records from the XMR1 wire creepmeter[1,3]; several examples are shown in Fig. 1. The small events usually have rise times similar to those for large events, but a few small events with shorter rise times (Fig. 1*c*, *e*) and with rise times of several hours (Fig. 1*a*, *g*) are also recorded. The distribution of event amplitudes at XMR1 is distinctly bimodal (Fig. 2). Another interesting feature is that small events at XMR1 preferentially occur during periods of several days just before large events (Fig. 3).

The suprising gap in the distribution of creep event sizes indicates that small events are not necessarily low-amplitude versions of the identical process acting over the same area of fault surface that produces large events. This being the case, there are at least two possible alternatives. The creepmeters may be measuring either the results of the same process operating on two distinctly different scales or the time-displacement signatures of distinctly different failure or propagation processes.

Strong evidence supports the first alternative in that large events usually propagate with a certain degree of regularity across several instrument sites[5,7], whereas small events usually appear at only one creepmeter at a time. Consequently, for small events that are observed, the point at which rupture begins must be very close to the instrument, and the minor slip probably is confined to a relatively small area of the fault surface. The lack of clear evidence for propagation of some of the smallest events over greater distances (≥ 0.5 km), however, could be because their amplitudes are commonly below the resolution of the non-wire creepmeters at sites adjacent to XMR1.

The concentration of small events just before large events indicates that the former are preferentially triggered at stress levels only slightly lower than those necessary for triggering large events. Small events recorded at XMR1 occasionally blend immediately into large events (Fig. 2*b*, *h*), perhaps owing to triggering of slip on a larger fault surface by the initial yielding of a small source area. The time relation reinforces the idea that small and large events result from the same process, with amplitudes determined by the area of the slip surface.

In contrast with this interpretation for the data from central California, results from a strainmeter array in Iran indicate that a small creep event (slip amplitude of about 10 μm) propagated more than 0.8 km along the fault break of the 1968 Dasht-e-Bayaz earthquake, as reported by King and others[11]. The strain results from Iran plus the wider range of rise times for small events than for large events at XMR1 provide some support for the possibility that different failure or propagation processes might be involved.

The explanation for large and small creep events involving a bimodal distribution of source areas implies a heterogeneous distribution of static friction along the fault surfaces that fail in episodic aseismic slip. Large events are perhaps prevented until conditions are favourable for nearly uniform propagation of aseismic slip over the entire large-event source area. The final stages of progress toward this condition probably are marked by a nearly uniform stress level slightly below that necessary for generating large events, but sufficient for initiating minor creep events across small, isolated, relatively weak patches of the fault surface within the source area for the impending large event. The small source areas are viewed as being quasi-permanent in position and dimensions. Slip action would cease after each small event until the general stress reached the threshold value for production of large events. Although many minor-event sources could be widely scattered across the large event area, only those adjacent to or encompassing a creepmeter site would produce detectable offsets. Activity on more distant small-source patches could produce certain small events with extremely long rise times.

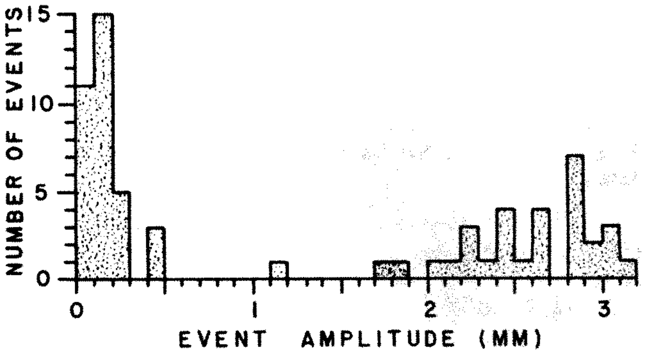

Fig. 2 Histogram of the number of events at wire creepmeter site XMR1 through 16 April 1976, as a function of slip amplitude. Similar bimodal distributions of event amplitudes have been demonstrated for several other sites but are less well documented on non-wire creepmeter records. A decrease in the number of events within the amplitude range 0–0.1 mm compared with the next higher range is probably a reflection of the limits of resolution; a number of small events with amplitudes less than 0.05 mm undoubtedly escape detection.

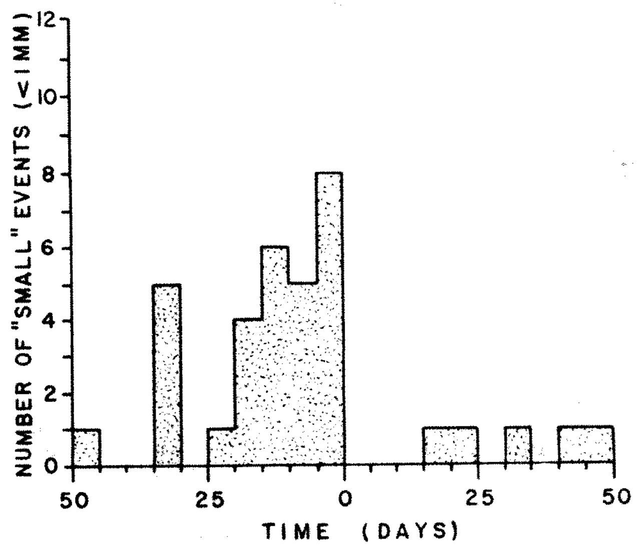
The expected behaviour of the proposed bimodal source-area system would seem to fit the observed distribution of event amplitudes, the concentration of small events during short periods just before large events, and perhaps the wide range of small-event rise times. The final small event leading to

Fig. 3 Distribution of onset times for small creep events in five-day increments before and after large creep events, from XMR1 records. The zero point on the time scale represents onset times for all large events recorded at the site.



general failure over the large-event source area could occasionally occur near a creepmeter, producing a composite event on the record for that site.

I thank Geoffery C. P. King, Keith Evans, C. Barry Raleigh, and James H. Dieterich for helpful comments; also Patricia A. Yamashita and Sandra S. Schulz for the preparation of data.

Loss of boron from shells during weathering and possible implications for the determination of palaeosalinity

The abundance of boron in sediments is frequently taken as an indication of palaeosalinity[1–6]. Because boron is readily absorbed by clay minerals, determinations are generally undertaken on argillaceous sediments, particularly those containing abundant illite, though some analyses are carried out on calcareous sediments. One of the basic assumptions of the boron technique for the determination of palaeosalinity is that there is little or no mobility of boron after deposition, as any mobility might lead to enrichment or depletion of the original boron, and an unreliable value for the palaeosalinity.

A recent study of a Holocene shell sequence from the central Queensland coast indicates a systematic decrease in boron content of the shells with increasing age. This could conceivably be due to a progressive change (that is, decreasing salinity) of the original depositional environment, but other lines of evidence do not support this. It seems more likely that the loss of boron is a consequence of sub-aerial weathering. This suggests that erroneous boron palaeosalinity results may be obtained from calcareous sequences which have been subjected to sub-aerial weathering.

During a study of the sedimentology[7] and geochemistry[8] of sediments at Broad Sound, on the central Queensland coast (Fig. 1), a series of elongate ridges (cheniers) were found, composed predominantly of whole and fragmentary shells. Radiocarbon dating of the shell carbonate revealed that the ridges became progressively older landward, ranging in age from 1,020 ± 70 yr BP to 5,450 ± 85 yr BP (ref. 8). This sequence offered a possible opportunity for quantifying the rate at which geochemical changes take place in calcaleous material under conditions of sub-aerial tropical weathering, or alternatively, for establishing the extent of environmental (temperature, salinity) changes which have taken place in the Broad Sound estuarine system during the last 5,000–6,000 yr. Because the chemistry of shells varies markedly with different phyla and species, the study was restricted to oyster shells, a bulk sample for analysis being prepared from 30–40 small oyster shells of approximately the same diameter, collected from eleven of the cheniers. In addition, modern oyster shells were also collected for analysis from an adjacent intertidal site. All shells were cleaned for 30 minutes in distilled water in an ultrasonic bath before analysis. The results of the boron analyses together with the radiocarbon ages and the proportion of acid-insoluble material are given in Table 1. X-ray diffraction analysis, carried out on all samples showed that the shells are composed of low-magnesian calcite with no significant change in the position of the main calcite peak. But the boron content varies somewhat; it is evident from a plot against radiocarbon age (Fig. 2) that boron decreases with age. Over a period of about 5,000 yr the mean boron content of the shells decreases to 40% of the present day content. Determination of the correlation coefficient indicates that the negative correlation between boron and age has a 99% confidence level.

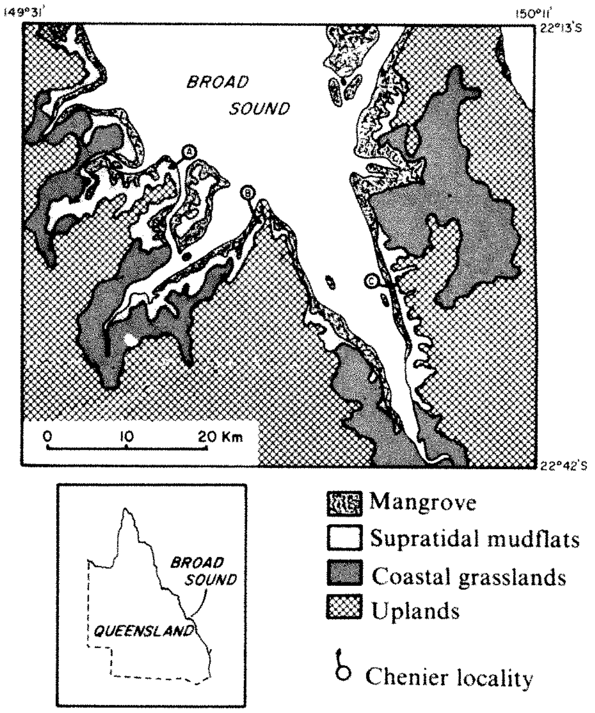

Fig. 1 Map of the Broad Sound area showing chenier locations from which oysters were obtained for this study.

Radiocarbon ages determined by H. A. Polach, Radiocarbon Laboratory, Australian National University, and R. Gillespie, Radiocarbon Laboratory, Sydney University. Boron was determined spectrophotometrically (using the organic reagent curcumin) by the Analytical Chemsity Section of the Australian Mineral Development Laboratories. Ten replicate analyses indicate a precision of ± 1 p.p.m.

Per cent acid insoluble determined by E. Kiss, Research School of Earth Sciences, Australian National University.

This change in concentration might conceivably be attributable to a progressive increase in salinity at Broad Sound over the past 5,000 yr. Kershaw[9-11] has suggested from palynological evidence that from about 6,000 to 3,000 yr BP the climate of North Queensland was significantly warmer and probably also wetter than the present-day climate. Broad Sound is situated at the confluence of four large estuaries but at the present day there is sporadic freshwater inflow only during the summer months (December to February) and even during this period, measurable dilution in the vicinity of the sampling sites lasts for only a few days. For almost the whole of the year, the water in Broad Sound and its associated estuaries shows complete vertical mixing and has a salinity of about 36 parts per thousand. The increase in rainfall required to have significantly affected the salinity of the Sound would therefore have needed to be of a far greater magnitude than that indicated by Kershaw's work. In addition, comprehensive stratigraphic studies[7], coupled with radiocarbon dating [12], indicate that since sea level stabilised at about 5,000–6,000 yr BP, depositional conditions have remained essentially constant. Therefore, it seems unlikely that the change in boron content can be attributed solely to a progressive increase in salinity at Broad Sound from about 5,000 yr BP to the present.

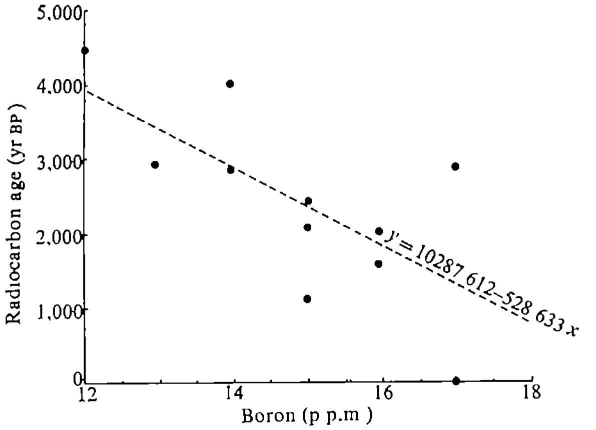

Fig. 2 Plot showing the progressive decrease in the boron content of oyster shells with increasing age.

An alternative explanation is that the decrease in boron content has occurred as a result of weathering. Because of the low concentration of boron in the shells it was not possible to determine the precise location of the boron. Normally, the boron in calcareous sediments is assumed to be in the detrital fraction, a correction factor being applied to determine the palaeosalinity[13]. However, the acid-insoluble fraction (composed entirely of clay-size material) proved to constitute on average no more than 1% by weight of the oyster shells (Table 1). If the mean boron content of non-calcareous clays is taken to be 160 p.p.m. (ref. 6), the acid-insoluble fraction will provide less than 2 p.p.m., or 10–15% of the total boron content of the shells. Also, there is no significant correlation between fraction of acid-insoluble material and the boron content. It therefore, seems most likely that the boron in oyster shells is mainly present within the calcite lattice, probably substituting for carbon. As chemical and X-ray diffraction results indicate that calcium carbonate is not preferentially leached from the shells, it would seem that substituted boron is being preferentially removed from the calcite lattice in oyster shells during the course of sub-aerial weathering. This might take place if the outer portion of the shells was boron rich but there is no reason to suspect that there is any such preferred location. Therefore, for the present it is only possible to point to the loss of boron during weathering without positively identifying the mechanism by which it is removed.

Returning then to the original point regarding the use of boron as an indicator of palaeosalinity. The Broad Sound results indicate that over a period of about 5,000 yr the boron content of oyster shells is considerably reduced. The extent to which these results from oyster shells may be extrapolated to other shells, and in turn to carbonate rocks in general, is uncertain. The results, however, undoubtedly suggest that errors may occur when taking the whole-rock boron content of carbonate rocks as a reflection of the original salinity, if those rocks have been subjected to sub-aerial weathering. It can perhaps be argued that where the boron content of the clay mineral only is considered that the problem of boron mobility is unlikely to arise. The Broad Sound study provides no information on the mobility of boron from clays. However, where the clay is in close proximity to shelly beds, and perhaps calcareous sediments in general, boron mobilised as a result of weathering is likely to be absorbed by the clay minerals. Where there is abundant shelly material this could conceivably result in a marked increase in the boron content of the associated clays, when compared with the original value. Further studies are necessary to fully assess whether the mobility of boron indicated by the Broad Sound study can be extended to calcareous and other sediments, and whether any such mobility limits the application of the boron method for the determination of palaeosalinity.

Pre-melting near crystal dislocations

IDEALLY, the melting of a crystalline solid should occur at a single temperature. In reality, the process is spread over a small range of temperatures. As the temperature approaches the nominal melting point T_m, the specific heat of, say, bismuth[1,2] acquires a component of the form

$$\Delta C = A/(T_m - T)^2 \qquad (1)$$

where A denotes a constant for a given sample. Usually the premonitory effect is attributed to the presence of impurities that dissolve only in the liquid phase. Indeed, an expression close to equation (1) can be derived on this basis. There is, however, good evidence[3] to indicate that the effect cannot be wholly due to Raoult impurities. In the present letter, we want to show that equation (1) also characterises pre-melting near point defects, while that occurring along edge dislocations is described by

$$\Delta C = B/(T_m - T)^3 \qquad (2)$$

where B denotes another constant.

Slater[4] in his classic paper on the ferroelectric transition of potassium dihydrogen phosphate indicates how a first-order transformation might acquire a temperature broadness at the hands of crystal imperfections. The same mechanism is invoked here to explain pre-melting. According to Slater, the stresses around crystal imperfections alter the effective pressure on the various crystallites and thereby cause them to undergo the transition over a small temperature interval.

To treat pre-melting formally, we can use the continuum model of solids. For mathematical simplicity we take the material to be elastically isotropic. Thus the effective pressure around a point defect varies inversely as the cube of the distance, while that near an edge dislocation goes inversely as the distance. Further, let us assume that the difference in the densities of the two phases is sufficiently small so that any stresses resulting from this difference can be neglected. Since transition curves are practically straight lines, the volume of a liquid domain developing around a point defect should go as $(T_m - T)^{-1}$ while that of a domain growing alongside an edge dislocation should be proportional to $(T_m - T)^{-2}$. Here we identify T_m as the temperature at which a crystallite subject to an effective pressure of 1 atm melts. Finally, using the fact that the change of entropy is proportional to the volume of the domains, we obtain for growth around point defects

$$\Delta C \propto T/(T_m - T)^2 \qquad (3)$$

and for development along dislocations

$$\Delta C \propto T/(T_m - T)^3 \qquad (4)$$

For most solids, the specific heat is anomalous over a temperature interval that is very small compared with the absolute temperature of melting. So relations (3) and (4) are virtually equivalent to equations (1) and (2), respectively.

The present findings lend themselves to a simple experimental test. First the anomalous component of the specific heat of a relatively pure bismuth crystal is determined. Then the crystal is severely deformed and the measurement is repeated. if sufficient dislocations are introduced, then the pseudo-critical exponent of its anomalous specific heat should go from −2 to −3.

Major genes for copper tolerance in *Mimulus guttatus*

HEAVY metal tolerance in higher plants has proved to be an excellent model system which has provided insight into several aspects of the evolutionary process (see ref. 1 for review). But comparatively little is known about the formal genetics of this character in higher plants, since the grasses which have been the subject of most of the ecological work are not readily amenable to genetic analysis. Antonovics *et al.*[1] argue that the data indicate that tolerance is governed by a polygenic system, though it has been shown that in yeast[2,3] and *Paramecium*[4] that major genes are responsible. The discovery[5] that the yellow monkey flower, *Mimulus guttatus,* has also developed copper tolerant races has enabled this hypothesis to be tested—the genetics of *M. guttatus* are readily investigated since it is easily destaminated and crossed, produces up to 400 seeds at a time, and can complete a generation in less than 100 d. The data presented here suggest that there are only two genes responsible for most of the tolerance observed in this plant.

A single plant (C10), typical of one of the most tolerant Californian populations, Copperopolis 4C, was crossed with a plant from the non-tolerant population at Cerig-y-drudion (for details of the populations see ref. 5). Forty F1 plants were tested for copper tolerance, and the most and least tolerant plants were then backcrossed to a Cerig plant. Twelve individuals of each of the F1 and the two backcross progenies were then grown in each of two fully randomised blocks. C10 was cloned, and 15 ramets of this plant and 15 Cerig individuals were also included in the randomisation. Because of the accidental loss of many of the plants from one block, a third block was later raised with 20 of each family. The data from all three blocks was pooled. Thus each family is represented by a maximum of 44 individuals. But, due to the death of some plants, and the fact that many individuals could not be tested at both levels of copper used in this experiment, the number of plants tested at any level is less than this.

The most immediate effect of heavy metals on non-tolerant plants is the inhibition of root growth[6]. This phenomenon provides the basis for the method of testing tolerance. Usually[7,8] an index is produced as the ratio of growth in a test solution to growth in a control solution, but in this instance, since we are concerned with the progeny of a single plant, the mean root growth of the

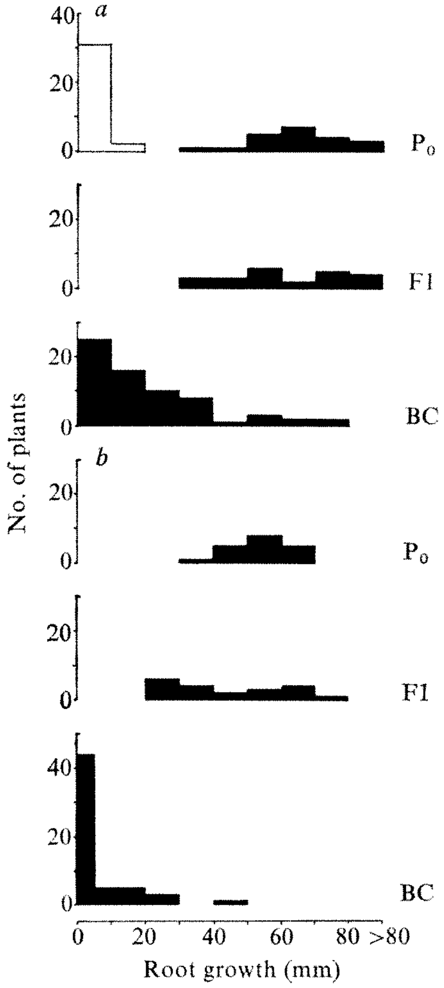

Fig. 1 Histograms of rootgrowth of P_0 (C10 filled, Cerig open), F1 and combined backcross (BC) progenies at *a*, 0.125 and *b*, 0.5 p.p.m. copper. Cerig plants were only tested at 0.125 p.p.m. since they all produce roots shorter than 2 mm at the higher level. The root growth of each plant is the mean of two cuttings grown for a week in a solution of 0.5% (w/v) $Ca(NO_3)_2$ containing the requisite level of copper as $CuSO_4$. Solutions were changed on the third and fifth days. Testing was performed at 23±1 °C with constant illumination. Note that not all plants could be tested at both levels. Full experimental details are given in ref. 9.

longest roots of two cuttings in a solution containing either 0.125 or 0.5 p.p.m. copper is used as the measure of tolerance. This method has the advantage that non-tolerants are more easily distinguished since at 0.125 p.p.m. they form short stumpy roots, while at 0.5 p.p.m. any roots which are produced die almost immediately.

Figure 1 gives the distribution of tolerance of the two parents, their F1 and the two backcross progenies, which have been pooled since they did not differ significantly (see Table 1*b*). At 0.125 p.p.m. it is apparent that the backcrosses contain many non-tolerant plants, but further conclusions at this level are limited by the large error inherent in measuring tolerance by this method. This error is revealed in Table 1, which gives the analysis of variance for each family at 0.125 p.p.m. More than 50% of the total variance of each of C10, Cerig and the F1 is due to measurement error (within plant variance). This variation is due to the natural variability of root growth: the principal source seems to be variation in the day of initiation (unpublished), though other factors are probably important (for example see ref. 10). Considerable genetic segregation in the backcrosses is indicated by the far larger proportion of its variance due to differences between individuals. Table 1 also shows that the C10, Cerig and F1 plants do not seem to be uniform at this level. The C10 ramets are genetically identical, and this variation is inexplicable in this instance. It is not found at other levels of copper in this clone, nor in two other clones tested. Significant differences within the Cerig population and the F1 family indicate that not all the individuals in these families are identical. In the case of the F1 this may indicate that C10 was heterozygous for some loci, but the lack of significant difference between the two backcross families indicates that this segregation is minor compared with the segregation in the backcrosses of loci homozygous in C10.

But at 0.5 p.p.m. Cerig plants are unable to form roots. Any that start to grow turn dark brown and die almost immediately. Any plant that shows any significant root growth must therefore be tolerant to a degree. The large error involved in tolerance testing is no longer so important because at this level we can make a qualitative distinction between tolerants (those plants which form roots) and non-tolerants (those that do not). All F1 plants are tolerant, but the backcrosses are segregating a large number of plants which effectively fail to root.

On this basis, the number of tolerant plants is 14, while there are 44 plants which are non-tolerant at this level. This ratio differs significantly from 1 : 1 ($\chi^2 = 15.5$), but not from 1 : 3 ($\chi^2 = 0.02$). A one gene model anticipates two equally frequent classes of progeny in the backcross, while a two locus model predicts three (AaBb; Aabb and aaBb; and aabb) in a 1 : 2 : 1 ratio, or 1 : 3 if the latter two classes cannot be distinguished. The data thus concord with a two-locus model, but not with a single gene hypothesis. The data at 0.125 p.p.m. can also be explained on a two locus model. Figure 2 shows the relationship between the tolerances at high and low levels of copper of plants tested at both levels. It is evident that, despite the high variation in testing, the correlation between tolerance at 0.125 p.p.m. and 0.5 p.p.m. is high. The plants which prove to be tolerant at 0.5 p.p.m. are mostly the plants with the highest tolerances at 0.125 p.p.m. But, there are still many plants which show greater root growth than Cerig plants at 0.125 p.p.m. but which show none at 0.5. On a two-gene hypothesis, in which only plants with both genes are tolerant, there is the problem of what the phenotype of a plant with only one gene is. These data would suggest that it could be partially tolerant at low levels of copper, but non-tolerant at higher levels.

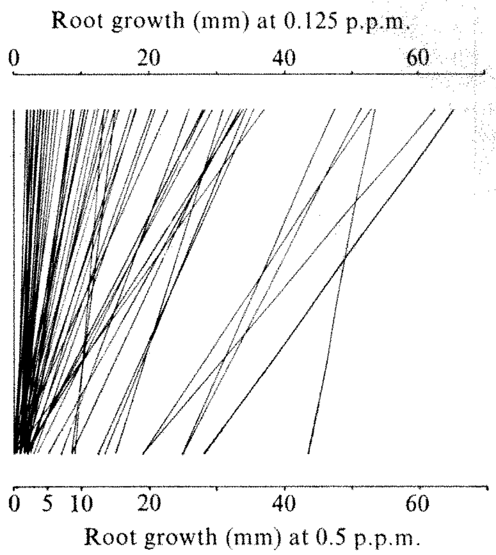

Fig. 2 The correlation between rootgrowth at 0.125 and 0.5 p.p.m. of the combined backcross progenies. All plants tested at both levels are included.

Models involving more than two genes of roughly equal effect would need to be complicated in order to fit these data. With three genes there are four classes with 0, 1, 2 and 3 tolerance genes respectively, and these are expected in a 1 : 3 : 3 : 1 ratio: it is difficult to see how the data can be explained on such a segregation. It is also apparent that at 0.125 p.p.m. there are many plants which are as non-tolerant as Cerig plants: the segregation of plants with no tolerance genes at all becomes progressively rarer as the number of genes postulated is increased.

The data presented here indicate that there are two major

genes involved in the production of copper tolerance in the Copperopolis population of this species. This conclusion is being tested by further breeding of the backcross progeny. However, these data do not rule out the possibility of there being other loci of lesser effect in addition. That this is likely is shown by the fact that crosses within the Copperopolis population reveal genetic variation[9]. All the Copperopolis plants tested were tolerant at 1.0 p.p.m., however, indicating that they were all homozygous for the two major genes.

This result has important physiological implications. Early work[11–13] on the physiology of tolerance suggested that zinc was bound up in the cell walls of zinc tolerant plants, thus preventing the metal from inhibiting cellular enzyme systems. Wainwright and Woolhouse[14], however, argue that this may not be the only mechanism, and showed that individual enzyme systems may show tolerance. These results were not repeated in studies on different systems[15,16]. If enzymatic adaptation were a major component of tolerance one would expect that there would be many genes involved in producing it, because heavy metals are general protein inhibitors. Unless there is one enzyme system which is much more susceptible to copper than others, the substitution of a single non-tolerant enzyme by a tolerant form is unlikely to increase the tolerance of the whole phenotype by a large amount. A compound that was able to bind heavy metals and reduce their effective cellular concentration could make a significant contribution to the overall tolerance of an individual, however. It is possible that the production of such a compound could be mediated by a few genes. Thus the finding that there seem to be only two genes in *M. guttatus* producing most of the tolerance observed in the highly tolerant Copperopolis population tends to implicate a primary physiological mechanism involving the production of a protein able to bind copper and render it unavailable to the cell, rather than a system of general enzymatic adaptation.

I am indebted to the late P. M. Sheppard, FRS for his advice and guidance while I was his student, and to Dr J. Bishop for critically reading the manuscript. I am grateful to NERC for a studentship.

Association of alleles at esterase loci in wild barley *Hordeum spontaneum* L.

THE aim of the conservation of plant genetic resources is to collect and preserve representative samples of genetic variation from the primitive 'landraces' and the related wild species of crop plants on which man depends for use in future breeding programmes[1,2]. Counter proposals[3] that breeders obtain specific alleles by mutagenesis at will are defensible when one is considering single loci. But groups of alleles at many loci which have jointly been subjected to natural selection, are unlikely to be assembled by mutation breeding. We report here the widespread occurrence of co-adapted combinations of alleles at the four esterase loci in populations of wild barley (*Hordeum spontaneum*) in Israel, thus reinforcing the case for genetic conservation.

Cultivated barley (*Hordeum vulgare*) is polymorphic for four esterase loci. Three of the loci, denoted *Est A*, *Est B* and *Est C* are tightly linked ($B \leftarrow 0.0023 \rightarrow A \leftarrow 0.0048 \rightarrow C$) and a fourth, *Est D* recombines independently[4]. In composite cross V, Allard and co-workers have described changes in gene frequency at these loci[5], and have shown that only a few specific combinations of alleles were favoured[6]. Similarly in composite cross II, two balanced arrays account for 33% of the gamete pool[7] after 26 generations. These esterase loci are also highly polymorphic among the accessions in the US Department of Agriculture barley collection[8] of the ancestral species (*Hordeum spontaneum*) (ref. 9). Here we report that natural populations of wild barley in Israel also exhibit only a restricted number of complementary arrays of alleles at the esterase loci.

Single seedlings from about 50 panicles sampled from each of 11 populations were subjected to starch gel electrophoresis. The populations form transects running east to west (numbered 1–8 in Table 1), and north to south (9–11) across Israel. All loci were scored in a leaf sample, and *Est A* and *Est C* were scored in a separate root sample. *Est D* was scored in only three populations. The alleles were assigned to mobility classes with respect to the commercial cultivars Atlas (SMFM), and Clipper (MMFS). (SMFM and MMFS refer to slow (S), medium (M) and fast (F) 'mobility classes' of esterases specified by loci *A*, *B*, *C* and *D* respectively when subjected to starch gel electrophoresis.) Table 1 lists the frequencies (f_{ijk}) of the two most common gametic arrays in each population. Thus, for example the 60% of the gametes in the Damun population were FSFM, 16% were MSMF and the remainder carried less frequent arrays. The observed number of alleles at each locus and the information at locus *X*

$$(I_X\ (= -\Sigma_j p_j \log_2 p_j))$$

(ref. 10) are listed. Most populations are appreciably polymorphic. However, the observed average heterozygosity was less than 0.01, because the outcrossing rate (t) was low ($0 < t < 0.02$).

Table 1 also lists estimates of two and three locus measures of allelic association at the specified esterase loci. These logarithmic measures are computed as $I_{XY} = \Sigma f_{ij} \log_2(f_{ij}/p_i p_j)$ ($f_{ij} > 0$) for two loci, and $I_{XYZ} = \Sigma f_{ijk} \log_2(f_{ijk}/p_i p_j p_k)$, ($f_{ijk} > 0$) for three loci[11,12]. There is a very high level of complementary association. For example, at Damun $I_{AC} \simeq \min(I_A, I_C)$ which is the theoretical maximum association in this case. Also $I_{ACD} \simeq I_{AC} + I_{CD}$ which is its theoretical maximum given the two locus values. The quantity ($1.38\ NI$) where N is the number of independent gametes in the sample ($N \simeq 50$), is distributed asymptotically as χ^2 with appropriate degrees of freedom. The values of I can be tested for departure from zero or lack of association. Virtually all tests indicated statistically significant association. Intense association between alleles over loci have been reported in natural Californian populations of wild oats[13]. There is also significant association between esterase loci in animals (salamanders[14] and *Drosophila montana*[15]).

The data from wild barley presented here highlight two important difficulties of interpretation which cannot be resolved unequivocally. First, there is disagreement concerning the extent to which allozyme polymorphisms are maintained by natural selection[16]. Furthermore, it is recognised in addressing this question, that the loci cannot be considered separately from the chromosomal segments to which they belong. Second, when there is total self-fertilisation, selection is not necessary to preserve associations of alleles between loci, since this mating system is sufficient to retain any associations generated sporadically by mutation or random drift and partial isolation[17].

*Association significant at the 5% level.
**Association significant at the 1% level.

However, provided there is some outcrossing and recombination, strong associations cannot persist in equilibrium populations if the chromosomal segments are neutral to selection[18,19]. We conclude that the occurrence of allelic associations for marker loci in natural populations of the wild relative of a crop plant is an observation crucial to the rationale of genetic conservation.

This research is part of a comprehensive survey of wild barley populations and is partly supported by grants from the United States–Israel Binational Science Foundation, Jerusalem, Israel to D.Z. and E.N. We thank Drs B. S. Weir and M. W. Feldman for comments.

Prediction of seed longevity at sub-zero temperatures and genetic resources conservation

THE International Board for Plant Genetic Resources (IBPGR) is encouraging the development of an international network of seed banks for the conservation of the genetic resources of the major crop species of the world and their wild relatives[1]. Most of the species in priority lists show 'orthodox' seed characteristics[2], that is their longevity is prolonged in a defined manner by a reduction in moisture content (MC) (at least down to 5% MC, fresh weight basis) and temperature[3]. From a consideration of biological factors and the design and cost of seed storage facilities, IBPGR recommends that orthodox seeds are stored at −18 °C or less and at $5\pm 1\%$ MC[2]. It is convenient to aim at −20 °C as the nominal temperature. Because of the accumulation of mutations associated with loss of viability[4,5], IBPGR recommends regeneration of stocks (that is growing plants to provide new seeds from the old) when viability has fallen by 5% (ref. 2). To plan ancillary facilities and procedures, it is necessary to estimate regeneration intervals (time taken for viability to fall by 5%) for the major crop species. Such estimates pose three problems: there are genotypically controlled variations in longevity within a species; seed 'quality', determined by conditions before harvest and during processing, can affect subsequent longevity; and loss of viability at −20 °C is extremely slow, and so far it has been possible to predict regeneration interval only by questionable extrapolation from more favourable storage conditions[4,6]. We have examined these problems in barley (*Hordeum distichum*, L.) and have developed an approach which should make possible more accurate predictions from experiments lasting only 2 yr—even though fresh seed of most species shows no detectable loss of viability during this time.

Loss of viability in orthodox seeds conforms closely to three basic viability equations applicable over a wide range of conditions in all seven species that have been examined in detail (Table 1) as follows[3,6]. The frequency of individual deaths in time in a population stored in constant conditions is described by the normal distribution

$$y = \{1/\sigma\sqrt{(2\pi)}\}\exp\{-(p-\bar{p})^2/2\sigma^2\} \quad (1)$$

where y is the relative frequency of deaths occurring at time p, $\bar{p}$ is the mean viability period, and σ is the standard deviation of the distribution of deaths in time. Consequently survival curves (percentage viability plotted against time) are cumulative normal distributions of negative slope, which become straight lines if transformed to probit (as in Figs 1 and 2). The spread of the distribution is directly proportional to the mean viability period, that is

$$\sigma = K_\sigma\bar{p} \quad (2)$$

where K_σ is a constant. And the relationship between moisture content, temperature and mean viability period is described by the equation

$$\log\bar{p} = K_v - C_1 m - C_2 t \quad (3)$$

where m is moisture content (% fresh weight basis), t is temperature (°C), and K_v, C_1 and C_2 are constants. Thus once the four viability constants (K_v, K_σ, C_1 and C_2) have been determined it is possible to define percentage viability after any period of storage in any combination of conditions.

We have examined five cultivars of barley (Vada, Berac, Julia, Golden Promise and Proctor) in various storage treatments and have found that the C constants have identical values ($C_1 = 0.098$ and $C_2 = 0.050$). Genotypic differences in longevity are attributable to differences in the value of the K constants: K_σ varies only slightly (mean value 0.214), but there are quite large differences in K_v, varying from 4.69 (when $\bar{p}$ is expressed in days) in Julia, to 5.56 in Proctor. Since K_v is related to log $\bar{p}$, this difference results in a sevenfold variation in longevity between the cultivars in identical storage conditions and, because the values of the C constants are identical, it follows from equation (3) that this relative difference is maintained in all storage conditions.

In experiments using Proctor we have investigated treatments on the seed crop which could affect subsequent viability, including nitrogen nutrition (15 or 70 kg ha^{-1} N), shading (intercepting 60% radiation for a month before harvest), degree of unripeness, and severity of threshing. Only shading and marked unripeness significantly affected longevity. As with genotypic effects, only the K constants were affected (K_σ only slightly). K_v was reduced from 5.56 to 5.54 by shading and to 4.70 by harvesting unripe seed. Thus only unripeness had a major effect, but this was as much as could be caused by genotypic effects. Now that it is known that both genotypic and prestorage environmental factors only have any practical effect on K_v, further estimates of possible variation in longevity within a species are greatly simplified.

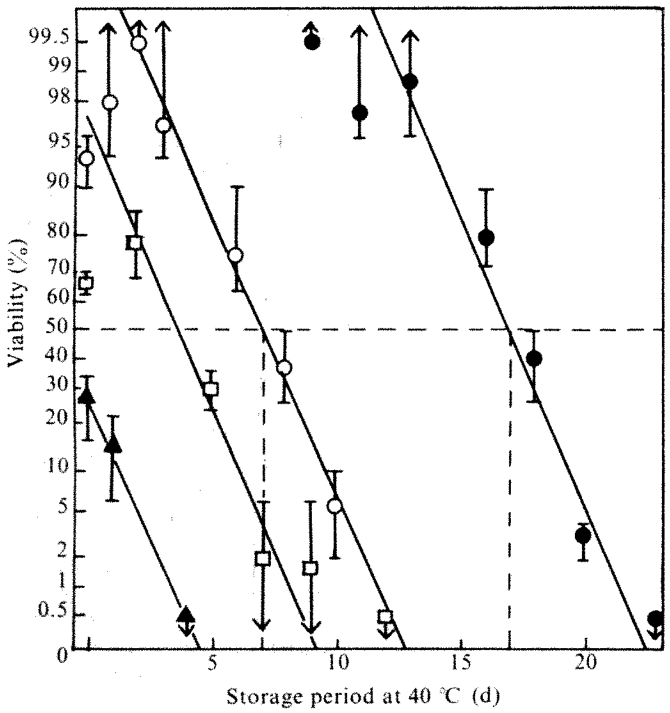

Fig. 1 Survival curves of barley seed (*H. distichum* cultivar Proctor) at 15.4% moisture content in hermetic storage at 40 °C after 0 (●), 3 (○), 4 (□), and 5 (▲) d previous storage at 50 °C. Percentage viability (mean of five replicates of 50 seeds each) is plotted on a probability scale. The vertical bars represent the extreme values of the replicates. Since 100% and 0% cannot be shown on a probability scale, such values are represented by arrows pointing upwards at 99.5% or downwards at 0.5%. Germination tests to determine viability were carried out at 7 d at 3 °C (to remove dormancy) followed by 14 d at 20 °C. Extension of the radicle by > 2 mm was taken to indicate a viable seed. Note that 3 d of preliminary storage at 50 °C had no significant effect on initial percentage viability, but decreased the mean viability period from 17 to 7 d.

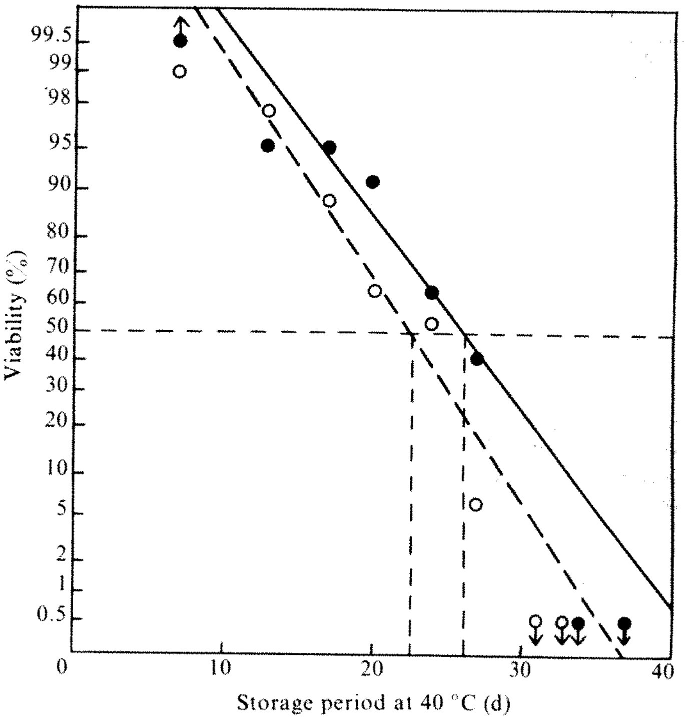

Fig. 2 The effect of 750 d of hermetic storage at −20 °C and 15.4% moisture content on the viability of barley seeds (*H. distichum* cultivar Proctor). Seed at 15.4% moisture content was hermetically stored at 40 °C. Paired samples were withdrawn at intervals and viability immediately determined on one sample (●). The second sample in each case was stored for a further 750 d at −20 °C after which viability was again determined (○). Each point represents the mean of four replicates of 50 seeds. Further explanation as for Fig. 1.

To develop a technique for estimating the very slow rates of deterioration which occur at sub-zero temperatures, it first had to be confirmed, using alternating temperature regimes, that change in temperature *per se* had no effect on longevity. It was then established that any preliminary seed deterioration did not affect the subsequent slope of the survival curve, but only the intercept: slope is determined solely by contemporary conditions (Fig. 1). Figure 2 shows that although 750 d of storage at −20 °C had no significant effect on initial viability, as would be expected from the shape of the survival curve, there is a maximum affect on percentage germination on samples approaching 50% viability. From the $\bar{p}$ values shown by the vertical broken lines, it can be calculated that 750 d of

Table 1 Provisional estimates of probable regeneration intervals for seeds stored at −20 °C and 5% moisture content

Species	Cultivar	Viability constants* K_σ	K_v	C_1	C_2	Probable regeneration interval (yr)†
Barley (*Hordeum distichum*)	Proctor, Golden Promise, Julia (mean values)	0.214	4.800	0.098	0.050	70

*Sources of values for viability constants: barley[7]; rice, calculated from figures supplied by Dr H. Ito[8]; wheat[9]; broad bean and pea[10]; onion[7]; lettuce, Dr Ann Minchin (unpublished results).

†Probable regeneration interval is calculated as predicted time for viability to fall to 95% of initial value (p_{95} period). Because 95% of the area under a normal curve (that is 95% of seed deaths) occurs when storage period $>\bar{p}-1.645\sigma$, it follows from equation (2) that $p_{95}=\bar{p}-1.645K_\sigma\bar{p}$. The value of $\bar{p}$ was solved by inserting the appropriate viability constants in equation (3) at 5% MC and −6 °C. The value −6 °C rather than −20 °C was chosen on the basis of the preliminary work on barley which indicated that equation (3) underestimates rate of loss of seed viability at sub-zero temperatures.

storage at −20 °C $\hat{=}$ 3.8 d of storage at 40 °C, that is, 1 d at 40 °C $\hat{=}$ 197 d at −20 °C. If C_2 has the same value at −20 °C, the predicted temperature, t_p, at which this result should have been obtained is given by $t_p = 40-(\log 197/C_2)$, that is −6.3 °C. Thus it seems that the rate of deterioration at −20 °C was greater than would have been predicted by extrapolation from higher temperatures.

These results have suggested an improved technique which we believe should be applied to the major crop species to estimate regeneration interval. It depends on the strong evidence that the value of K_σ remains the same in all storage conditions[3,7]. If a sample were reduced to about 50% viability by rapid ageing (for example, storage at 40 °C at about 15% MC), it could then be stored at −20 °C for, say, 2 yr when significant losses of viability would be expected. Sequential germination test over this period would determine the slope of the survival curve from which σ, $\bar{p}$ and K_σ could be calculated (equation (2)). Similar treatments at several other moisture contents and sub-zero temperatures would provide additional values of $\bar{p}$, making possible simultaneous solution of equation (3) and providing the values of all four viability constants determined in conditions approximating those recommended, and avoiding the need to extrapolate from higher temperatures.

Further work is needed, but will take a few years to complete. Meanwhile practical decisions have to be made, and it is suggested that at present best estimates of regeneration interval are obtained by applying the three viability equations and the four viability constants determined at higher temperature to predict the time taken for viability to fall by 5% at −6 °C (because extrapolation to −20 °C seems to underestimate the rate of deterioration at that temperature). Although such estimates (Table 1) may be far from perfect, they suggest that in the conditions recommended by IBPGR, seeds of many species are stored without regeneration for more than a century; but some species may need to be regenerated in less than 20 yr. Because longevity is affected by both genotype and pre-storage environment, it is essential that stocks are monitored for loss of viability at intervals which relate to expected longevity. It is not sufficient, however, to be guided entirely by the expected time for viability to fall by 5% (p_{95} period). The seed-to-seed variation in longevity (described by K_σ) which determines the slope of the survival curve is also important, because a species with a low K_σ value will give relatively little warning of an impending fall in viability (for example, lettuce in Table 1), and such species should be monitored more frequently.

Night flight towards a sex pheromone source by male *Spodoptera littoralis* (Boisd.) (Lepidoptera, Noctuidae)

Pheromones have been used in population monitoring traps[1] and in control by 'confusion'[2], and a good understanding of how the male finds the female is of great practical importance in the development of these techniques. The problem of insect orientation towards distant odour sources is also intrinsically interesting and much work has been done with wind tunnels to study the flight of moths in attractant plumes (the most recent of many reports is ref. 3). These studies have shown that moths fly upwind in a series of horizontal zig-zags which decrease in amplitude as the source is approached. Field observations support these general findings[4], but they are not as detailed as the results of laboratory studies and the techniques are not suitable for night flying species, many of which have considerable economic importance. We describe here techniques for observing and recording the details of the behaviour of night flying insects in attractant plumes, and also some new findings which suggest that flight towards a sex pheromone source in one species consists of several distinct stages with deviations from a straight upwind path taking place largely in the vertical plane.

The work was carried out in Crete during August and September 1975 and 1976 as part of experiments on the use of sex pheromones to control *Spodoptera littoralis* (Boisd.), a noctuid moth, the larvae of which damage many crops, including lucerne and cotton. For flight trials the synthetic sex attractant pheromone *cis*-9, *trans*-11-tetradecadien-1-yl acetate[5] was used, dispensed from a cylindrical polythene vial 3 cm long and 1.5 cm in circular cross section diameter, giving a release rate of order 5 ng min^{-1}. This was suspended 1 m above the ground in lucerne 0.2–0.3 m high. Even in bright moonlight *S. littoralis* males cannot easily be seen beyond about 2 m and to see moths at greater distances a night-viewing device (NVD) was used. This consists of a cascaded set of photomultiplier tubes, giving a light magnification of order ×40,000 (ref. 6) and optics which produce an image magnified ×2.5. In field conditions a grey object of 5 cm^2 can normally be seen at 25 m in bright starlight. The instrument has a very large object lens, however, and therefore a large effective aperture; at the desired ranges, of order 20 m, the depth of field is inadequate for small moving targets. Also the image at low light levels is coarse grained and scintillates strongly. Both of these limitations have been overcome by using supplementary infrared illumination which greatly improves image brightness and definition in the NVD and facilitates the use of aperture disks effectively to 'stop down' the object lens, thereby increasing depth of field. With a 4-mm aperture, the depth of field at 25 m is about 10 m. Two 55-W car spotlights were placed 16 m apart on the windline through the attractant source and shining towards each other and the source, with the upwind lamp some 6 m from the attractant. The beams were filtered by infrared gelatine filters (Wratten 87) which nominally pass light in the wavelength range 750–1,000 nm only, well beyond the sensitivity found in the eyes of most insects except at very high intensity[7].

Flight behaviour was observed both from a position 10–20 m to the side of the expected flight path and from upwind of the source looking along the path. Portions of the flight path were recorded in side view by two methods. A 16-mm cine camera recorded the NVD image, and infrared-sensitive film was used in a 35-mm still camera with a sector shutter giving a series of images of the moth's flight on one frame. Figure 1 shows the last few metres of a flight as an example of the latter method, and Fig. 2 shows a reconstruction of a flight path made by superimposing drawings of the moth's position taken from a series of consecutive frames of cine film. From the measured and scaled time interval, the actual speed of the insect along its flight path relative to the ground (the 'speed of flight') and its horizontal component, the ground speed, can be calculated. Both techniques make it possible to see the heading of the moths and on the 35-mm frames the body angle of attack can also be seen.

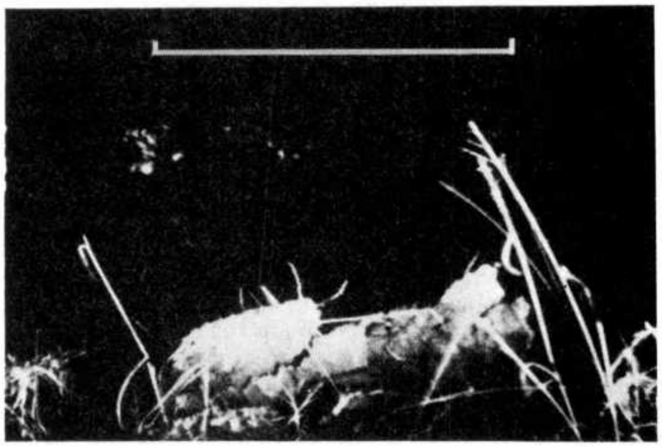

Fig. 1 Multi-exposure infrared photograph showing 'undulating' and 'hovering' flight. Scale shown is approximately 1 m. Inverval between successive frames was approximately 1/30 s. Wind was from the left.

Male moths showed a surprisingly consistent flight pattern and in favourable conditions (a steady wind greater than 0.25 m s^{-1}) distinct successive stages of flight were found, performed by some 90% of about 1,000 moths identified as *Spodoptera littoralis* on the strict criterion of their halting their forward progress on the pheromone capsule or in the air close to it. (Some insects of about the size of *S. littoralis* flew straight upwind past the capsule without any apparent recognition of it; it is possible that some of these may have been *S. littoralis* males, but they were discounted.)

Figure 3 shows the general flight pattern. In steady wind the moths were first seen in straight and level flight, making rapid progress directly upwind with an estimated ground speed of 3 m s^{-1} and at an altitude of between 0.5 m and 2.0 m; this portion of the flight was outside the field of view of the cameras. At a distance from the source usually within the range 2–4 m, and apparently fixed for a given wind speed, the moths abruptly reduced both ground speed and 'speed of flight', performing subsequently a slower, more undulating flight of about 0.5 m s^{-1}. This is shown in Fig. 1 up to about 0.5 m from the source and in Fig. 2 up to about 0.2 m. Although the flight path contained some deviations in the horizontal plane, well defined zigzagging took place only as undulation in the vertical plane.

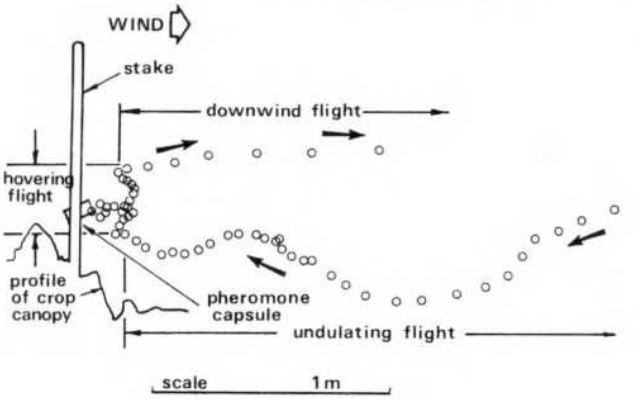

Fig. 2 Flight track produced from ciné film. The circles represent the moth's position on consecutive frames.

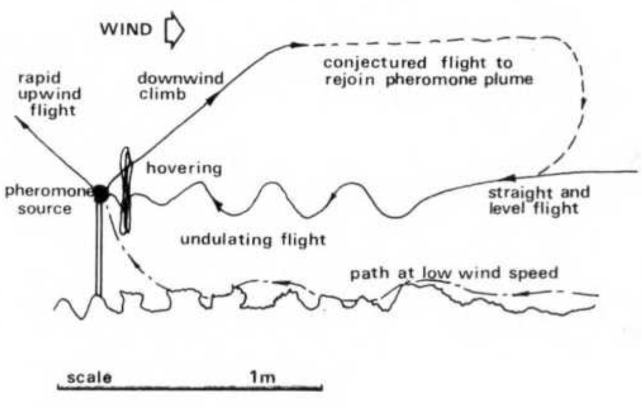
Closer to the source, forward progress was halted and vertical oscillations increased until the moth was hovering downwind from the source and moving up and down over a distance of up to 1 m while maintaining its upwind heading (Figs 1 and 2). Hovering could last up to 10 s during which occasional, less regular, short, downwind flights and general exploratory movements were made. About half of these moths then turned and flew rapidly downwind, often climbing to an altitude of order 2–3 m where they were usually lost from view. About half of them again landed near or on the capsule and moved about rapidly in a small area, often fanning with the wings. In Fig. 2 the moth very briefly touched the capsule before flying away in a gentle downwind climb accelerating to 2.2 m s^{-1} by the last frames. The moths which did land usually settled for up to about 1 min before leaving the capsule either downwind or in a rapid climbing upwind flight, again generally out of the illuminated region. On five nights moths were observed from a greater distance, 30–40 m, and it was then possible to see them climbing from the capsule and at an altitude of some few metres swiftly turning to head and fly downwind and then dropping to the original approach height about 10–20 m from the source. It was very difficult to see the moths after this because the image they produced in the NVD at such distance could be confused with

Fig. 3 Generalised flight pattern and the effect of low wind speed on it.



that produced by the lucerne leaves, but on two occasions it was possible to see them flying towards the attractant source again. At lower wind speeds the initial stages of the approach flight were made at very low altitude; in winds below about 0.1 m s^{-1} moths flew within the crop canopy, from which they made the final approach in a climb which became steeper as wind speed became less.

The observations suggest that the flight of male *Spodoptera littoralis* to a pheromone source is made in discrete stages with different flight patterns and perhaps also different orientation mechanisms. The flight paths observed showed a strongly vertical undulation pattern which contrasts with the horizontal zig-zagging more generally seen. This is not understood, but it may be due in some way to differences in the structure of the pheromone plume.

We thank Dr R. F. Chapman, Dr D. G. Campion, Professor J. S. Kennedy and Mr D. E. Pedgley for helpful discussions.

Effect of regeneration on compartment specificity of the bithorax mutant of *Drosophila melanogaster*

IN insect imaginal disks the basis for determination may be the state of a series of loci, each switched on or off in a given cell lineage at a unique point in development known as a compartmentalisation event[1]. Clones induced after the blastoderm stage define homologous anterior and posterior compartments in the thoracic disks[2]. Bithorax mutants transform the anterior compartments of the metathoracic disks (haltere and third leg) into those of the mesothorax (wing and second leg); however, a wild-type allele must function continuously until metamorphosis to prevent the transformation[3,11]. This suggests that permanent activation of the gene at blastoderm accounts for heritability of the determined state. Compartmental commitments are apparently lost when disk fragments regenerate[4,5]. We therefore studied duplication patterns in the third legs of a temperature-sensitive cell-lethal mutant also homozygous for bithorax. Heat treatment of these larvae kills cells, producing disk fragments which regenerate *in situ* giving duplicated appendages[6–8]. We report here that bithorax sometimes transforms posterior compartments of duplicated legs, showing that its effects are not invariably compartment-specific.

Duplicated and deficient (DFP) third legs from heat-treated *726; bx^{34e}/MT6* or *726; bx^{34e}/bx^{34e}* individuals were scored for several morphological markers that differ between meso-and metathorax. 'Original' and 'duplicate' members of DFP legs could be distinguished on the basis of symmetry and size. Control data were collected by scoring unduplicated legs from the same flies and from a sample of bx^+ controls. The results are presented in Table 1. The bx^+ data demonstrate the reliability of the markers. The only marker that lacks complete specificity is the 'hairy island bristle' (BH^-). This is invariably present in mesothoracic legs, but also appears in the metathorax, especially in *TM6* heterozygotes. The data from bx^{34e} and bx^{34e}/*TM6* flies should therefore be compared only with the appropriate controls when this marker is considered.

Among bithorax third legs we found only markers of the mesothorax in the anterior compartments. In the posterior compartments of unduplicated legs and original members of DFPs we found only metathoracic markers (rows 5–8 of Table 1). But, in the posterior compartments of duplicate members we found markers of both meso- and metathorax (rows 9 and 10).

These results clearly show (1) that the effect of bithorax is confined to the anterior compartment of the unduplicated third leg, as in the haltere, (2) that the penetrance of the bx^{34e} allele is complete in the leg, and (3) that when the leg duplicates, the posterior compartment of the duplicate is sometimes also transformed. The transformation usually affects every marker in the compartment. Only 2 out of 50 cases are putative exceptions, each having a single discordant marker. Examples of the two major classes of duplication are illustrated in Fig. 1.

The posterior compartment of the duplicate was transformed to mesothorax in 18 out of 50 DFPs. The incidence of transformation was not significantly different in the two genotypes tested (Table 2*a*). The possibility that trans-

Table 1 Number of times markers of meso- and metathoracic legs were present in samples of duplicated third legs and in controls

Experimental flies were obtained by breeding from a *yvf726*; bx^{34e}/*TM6* stock. The symbol '*726*' refers to a temperature-sensitive lethal allele, *l(1)ts726*, at the suppressor-of-forked locus (1-65.9). When larvae carrying *726* are placed for 48 h at 29 °C, pattern deficiencies and duplications (DFPs) are formed in the surviving adults[6]. Cell-death creates disk fragments that duplicate during the extended larval period caused by heat treatment[7]. Leg deficiencies affect contiguous sets of markers located medially on the fate map[8]. bx^{34e} is an allele at the bithorad locus (3-58.8). The third chromosome balancer *TM6* carries the markers bx^{34e} and Ubx^{67b} (Ultrabithorax; 3-58.8) which is lethal as a homozygote. Further details may be found in Lindsley and Grell[9]. Homozygous bx^{34e} progeny were distinguished from bx^{34e}/*TM6* heterozygotes by scoring the halteres which are much more strongly transformed when *TM6* is present. Parents were allowed to lay eggs for 5 d at 22 °C in bottles containing a standard medium[6]. The parents were discarded and the cultures shifted to 29 °C for 48 h then returned to 22 °C. On eclosion, adults of appropriate genotypes were collected and examined for duplications. Pharate adults that failed to eclose were dissected from the pupal case and treated similarly. Flies with duplications were dissected and mounted for detailed examination as described elsewhere[8]. Morphological markers were scored under the compound miscroscope. For details of markers used see Fig. 1 legend. Markers were assigned to compartment following Steiner (1976)[2].

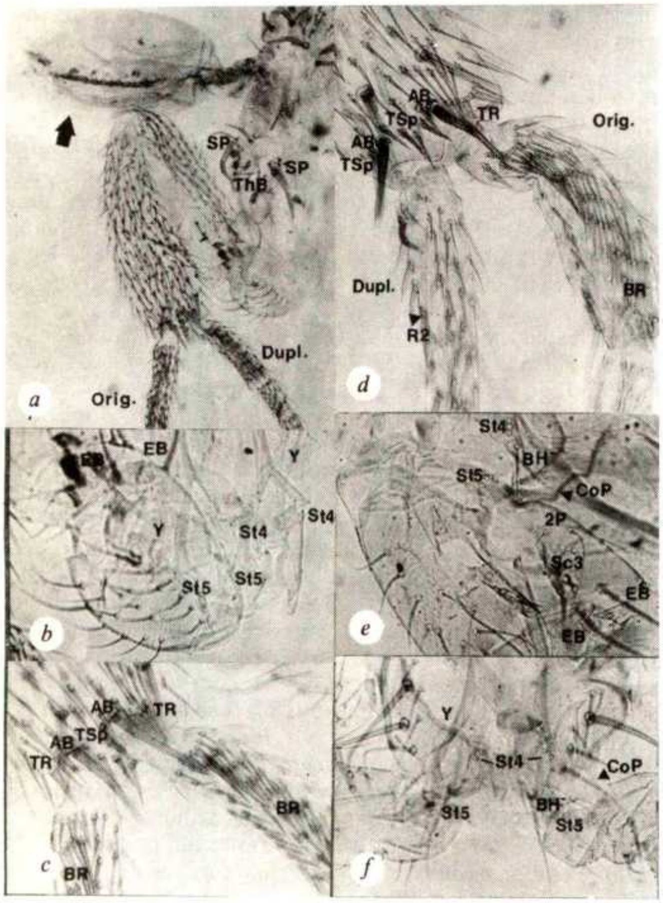

Fig. 1 *a–c*, DFP third leg in a $bx^{34e}/TM6$ fly; *b* and *c* show details of markers in proximal and distal segments. Anterior haltere is transformed into wing (arrow). Anterior compartments of both original and duplicate parts of leg bear mesothoracic markers: sternopleurals (SP), thoracic bristles (ThB), edge bristles (EB) and apical bristles (AB). The posterior compartments of both elements bear the following metathoracic markers: the Y-shaped apodeme (Y), tibial transverse row (TR), basitarsal transverse rows (BR). *d–e*, DFP bx^{34e} third leg. The duplicate posterior compartment is transformed into that of the second leg. In *d* note tibial spurs (Tsp) flanking the apical bristle on both sides in the duplicate, and on one side in the original. Duplicate also has a single row of bristles (R2) in the basitarsus where the original has transverse rows (BR). Coxa and trochanter are shown in *e*. Markers in the focal plane belong to the duplicate posterior compartment, and are characteristic of the mesothoracic leg. BH^-, hairy island bristle; CoP, coxal process; 2P, bristles proximal to Sc3. St4, St5 and Sc3 are found in both meso- and metathoracic legs (compare Fig. 1*b*). *f*, DFP 3rd leg in which duplicate is mesothoracic. This example shows the Y-apodeme in the original leg (Y) with arms adjoining St4 and St5. This clearly is not present in the duplicate, which instead shows a hairy island bristle (BH^-) and a coxal process (CoP).

formation depends on stage at heat treatment is ruled out by the fact that in four out of five cases in which both third legs from the same fly were duplicated, one was transformed, and the other was not. We also scored each DFP for a series of morphological markers common to meso- and metathoracic legs. Deficiencies for these markers may either fall entirely within the anterior compartment, or may also extend into the posterior[8]. Posterior cells might be expected to participate more often in the formation of the regeneration blastema in the latter event. Contrary to expectation, no significant difference in the frequency of transformation was found (Table 2*b*).

Table 2 Incidence of transformation of posterior compartment of duplicate, classified by *a*, genotype and *b*, extent of deficiency

	a Genotype		*b* Deficiency	
	bx^{34e}	$bx^{34e}/TM6$	Anterior only	Anterior and Posterior
Transformation				
Anterior only	21	11	21	11
Anterior + posterior	10	8	13	5
Contingency χ^2	0.49		0.23	

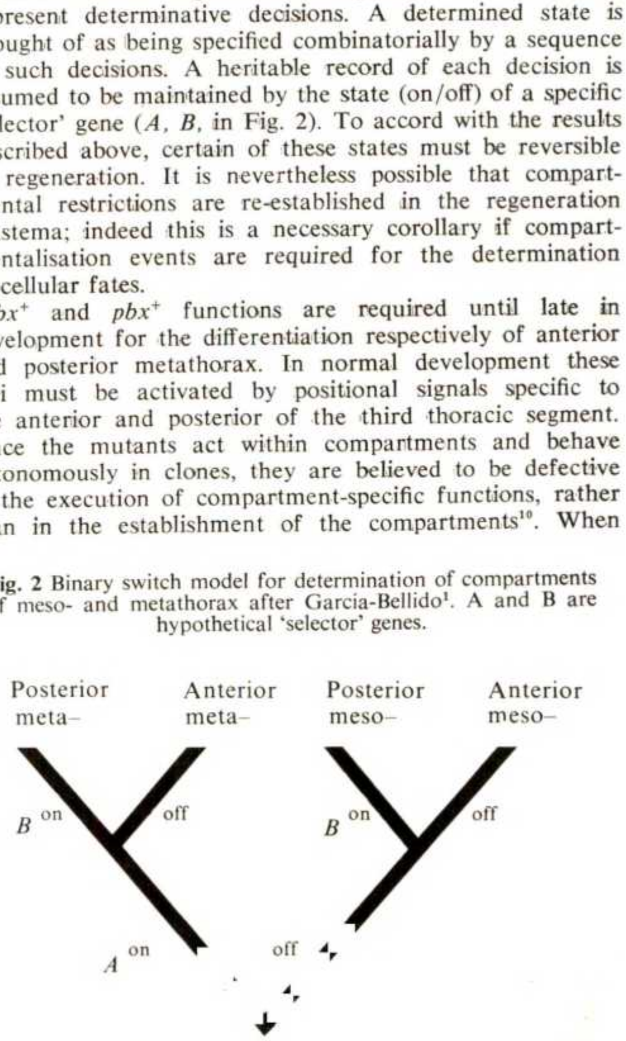
The following interpretation is tentative, but susceptible of verification. Transformation of the duplicate posterior compartment implies that the regeneration blastema is sometimes derived from anterior cells in the original leg. Schubiger[4] showed that anterior fragments[2] can regenerate an entire leg, and Haynie and Bryant[5] have confirmed that regeneration across compartment boundaries can occur. In bithorax homozygotes, anterior cells normally develop as mesothorax. Our results suggest the transformed state may be maintained when these cells form the posterior compartment of the duplicate.

Classification of DFPs by size of deficiency provides no support for the idea that regeneration of a metathoracic posterior compartment depends similarly on recruitment of posterior cells from the original leg. Although we have no direct evidence we prefer the alternative hypothesis which assumes that anterior cells have some finite chance of changing state when they enter the regeneration blastema. The work of Adler (personal communication) provides direct support for this interpretation. Anterior fragments of bx^3 haltere disks were occasionally able to form posterior haltere when stimulated to regenerate across the compartment boundary.

Garcia-Bellido[1] argues that compartmentalisation events represent determinative decisions. A determined state is thought of as being specified combinatorially by a sequence of such decisions. A heritable record of each decision is assumed to be maintained by the state (on/off) of a specific 'selector' gene (*A*, *B*, in Fig. 2). To accord with the results described above, certain of these states must be reversible in regeneration. It is nevertheless possible that compartmental restrictions are re-established in the regeneration blastema; indeed this is a necessary corollary if compartmentalisation events are required for the determination of cellular fates.

bx^+ and pbx^+ functions are required until late in development for the differentiation respectively of anterior and posterior metathorax. In normal development these loci must be activated by positional signals specific to the anterior and posterior of the third thoracic segment. Since the mutants act within compartments and behave autonomously in clones, they are believed to be defective in the execution of compartment-specific functions, rather than in the establishment of the compartments[10]. When

Fig. 2 Binary switch model for determination of compartments of meso- and metathorax after Garcia-Bellido[1]. A and B are hypothetical 'selector' genes.



bx^+ pbx^+ third legs duplicate, the posterior compartment is always metathoracic. In the context of the model this implies activation of pbx^+ and thus, heritability of the decision that distinguishes meso- from metathorax. Transformation of the duplicate posterior compartment when the genotype is bx^- pbx^+ therefore implies that bx^+ function is necessary for heritability of this decision. If a memory of the determinative event existed in the state of an independent selector gene (A in Fig. 2), we would not expect a mutation at bithorax to influence activation of postbithorax. Application of magnetic microspheres in labelling and separation of cells

POLYMERIC microspheres conjugated to antibodies and lectins have been used previously as cell surface markers for the detection and localisation of antigens and lectin receptors using scanning electron microscopy (SEM) (refs 1–4). In this report we describe a new, more versatile cell surface probe consisting of iron-containing polymeric microspheres tagged with fluorescent dyes and chemically coupled to antibodies or lectins. The magnetic and fluorescent properties of these microspheres have been utilised in the magnetic separation of red blood cells (RBC) and lymphoid cells and in the detection of immunoglobulin (Ig) receptors and wheat germ agglutinin (WGA) receptors on lymphocytes and Hela cells by SEM and fluorescent microscopy.

Magnetic, polymeric microspheres were synthesised from iron oxide (Fe_3O_4) particles (Ferrofluidics, Burlington, Massachusetts, No. A01, 5%, w/v) and from methyl methacrylate (MMA), hydroxethyl methacrylate (HEMA), methacrylic acid (MAA), and ethylene glycol dimethacrylate (EGDA) purified as described previously[1,2]. Briefly, a mixture of 1.6 g MMA, 0.9 g HEMA, 0.3 g MAA, 0.2 g EGDA, 1 g iron oxide suspension and 1 g Triton X-405 was de-aerated and polymerised by Co γ irradiation (0.2 Mrad at 0 °C for 60 min)[5]. The Fe microsphere suspension was purified on a mixed-bed ion-exchange column[1] and centrifuged at 30,000*g* for 45 min at 4 °C on a discontinuous gradient consisting of 20% (w/w) sucrose in the upper layer and 60% (w/w) in the lower layer. Three fractions (brown in colour) were recovered: an upper band in the 20% sucrose fraction (Fe content 6.2%); a lower band in the 20% sucrose layer (Fe content 28.4%); and a pellet (Fe content 42.4%). The upper and lower fractions were used in cell labelling studies. The average size of these particles was 40 nm as measured by SEM.

Copolymer Fe microspheres were derivatised with diaminoheptane by the cyanogen bromide method[1,6] and tagged with 1 mg fluorescein isothiocyanate (FITC) per ml suspension in carbonate buffer, *p*H 9.5, for 12 h at 25 °C. After removal of excess FITC, the spheres were re-derivatised with diaminoheptane using the carbodiimide method[1].

Affinity purified antibodies or lectins were coupled to the fluorescent Fe microspheres by the two-step glutaraldehyde reaction[1,7]. A protein concentration of 0.5–1.0 mg ml^{-1} and a Fe microsphere concentration of 1 mg ml^{-1} was used in the coupling stage. The reaction was carried out for 5–12 h at 25 °C. Unbound protein was separated from the protein–microsphere conjugate either by centrifugation on a discontinuous sucrose gradient[1] or by chromatography on Sepharose 6B. The conjugates could be concentrated with a magnet placed against the wall of a glass vial.

The application of magnetic immunomicrospheres in the separation of cells was tested in two independent systems. In the first, glutaraldehyde-fixed mouse thymocytes indirectly labelled for surface antigens with fluorescent–Fe microsphere–antibody conjugates were mixed in varying proportions with unlabelled human RBC. The mixture was layered over phosphate-buffered saline (PBS) containing 5% bovine serum albumin (BSA) and placed in a magnetic field (horseshoe magnet, 12 lb pull). After 2 h the solution was eluted to separate cells attracted to the magnet from those that were not. Differences in cell morphology and fluorescent labelling were used to analyse the cell fractions. The rate of deflection of labelled cells towards the magnet depended on the extent of labelling and the Fe content of the microspheres. As indicated in Table 1, over 99% of the labelled thymocytes were attracted by the magnet.

In a more applicable system, this technique was used to separate out lymphocytes displaying Ig receptors (B cells) from a mixed population of spleen lymphocytes. Fluorescent Fe microspheres coupled to goat anti-mouse Ig were used to directly label unfixed lymphocytes. Labelled cells could be readily distinguished from unlabelled cells under a fluorescent microscope (Fig. 1). In agreement with literature values[8,9] approximately 37% of the cells were labelled (Table 1). The mixture of labelled and unlabelled cells was subjected to a magnetic field. Previous removal of unbound Fe microspheres was not necessary. After 2 h at 4 °C, 97–99% of the labelled cells (principally B lymphocytes) were retained by the magnet, leaving a highly purified population of unlabelled lymphocytes (T cells). Some unlabelled cells, however, were also in the cell population which was retained by the magnet. This resulted largely from nonspecific aggregation of the lymphocytes and nonspecific adhesion of cells to the glass wall of the pipette. Further removal of unlabelled cells from the predominantly labelled cell population could be achieved by a second passage of dissociated cells through the magnetic field. A detailed study of optimal conditions for cell separation will be given elsewhere.

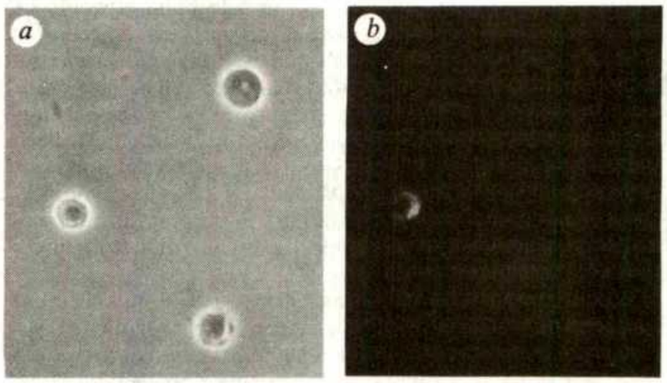

Fig. 1 Mouse spleen lymphocytes directly labelled for surface immunoglobulin (Ig) receptors with fluorescein–Fe microsphere-goat anti-mouse Ig antibody conjugates. *a*, Lymphocytes viewed by phase contrast light microscopy. *b*, The same lymphocytes viewed by fluorescent microscopy. Only one lymphocyte (B cell) is labelled with the conjugates.

Application of these fluorescent Fe-microspheres as visual markers for SEM was also demonstrated. Figure 2*a* illustrates the labelling of wheat germ agglutinin receptors on cultured Hela cells. Specificity was verified by the absence of binding of the

Table 1 Magnetic cell separation

Experiment	Before separation No. of cells counted Total	 Labelled (Fl)*	% Labelled (Fl)	Magnet	After separation No. of cells counted Total	 Labelled (Fl)*	%Labelled (Fl)

				Not attracted	303	9	3.0

*Labelled with fluorescein–Fe microsphere–antibody conjugates.

In RBC-thymocyte experiment 1, 2.1×10^6 glutaraldehyde-fixed RBC were mixed with 8.2×10^6 fixed mouse thymocytes labelled sequentially with rabbit anti-thymocyte antiserum followed by fluorescein–Fe microsphere–goat anti-rabbit immunoglobulin conjugates. Experiment 2 was carried out in similar conditions, except that 8.1×10^6 RBC were mixed with 3.3×10^6 thymocytes. The number of fluorescent cells was measured. Approximately, 5×10^6 mixed cells were layered on a 5% BSA–PBS solution. A magnet (12 lb pull) was placed against the wall of a 0.9-cm diameter column at the interface. After 2 h at 4 °C the column was gently eluted with PBS to separate cells attracted to the magnet from those which were not. The magnet was then removed from the side of the column, and the cells pulled to the side of the column were displaced by shaking the column. The two cell fractions were analysed for fluorescent (Fl) labelling and for cell type using a Leitz Dialux fluorescent microscope. In experiments 3 and 4, 1×10^6 mouse spleen lymphocytes purified by the Ficoll isopaque method[13] were directly labelled with 0.1 ml fluorescein–Fe microsphere–goat antimouse Ig conjugates at 4 °C. Cells were washed and the percentage of cells with fluorescein label was measured. Approximately 5×10^5 cells were then layered on a Ficoll isopaque layer and subjected to magnetic separation as described above.

WGA–microsphere conjugate in the presence of *N*-acetylchitobiose, an inhibitor of WGA (Fig. 2*b*).

These new cell surface reagents have potential applications in biochemical and microscopic studies of specific components on cell surface membranes. The magnetic properties of these spheres can be utilised to isolate specific types of cells. The magnetic cell sorting technique described here is quite simple, but more sophisticated instrumentation can be envisioned to continuously separate cells which differ in the number, as well as the nature of surface molecules. Such techniques would be particularly useful for processing large numbers of cells for biochemical and immunological studies. Magnetic properties can also be used in the separation of labelled cell surface membranes from intracellular membranes, as well as in the purification of specific membrane-bound receptors which have been solubilised in mild detergents. Stronger magnetic fields may be required in such applications. Alternatively, the dense properties of these spheres can be exploited to separate membranes and receptors by density or velocity perturbation techniques using ultracentrifugation[10,11].

The iron content of these microspheres also permits their use as visual markers for transmission electron microscopy (TEM). This enables one to correlate labelling information derived from light and SEM with cellular ultrastructure obtained by TEM. In principle, similar reactions used in the synthesis of these iron-containing polymeric spheres can be adapted for preparing microspheres containing gold or other heavy metals which have advantages for SEM and TEM (refs 4, 12).

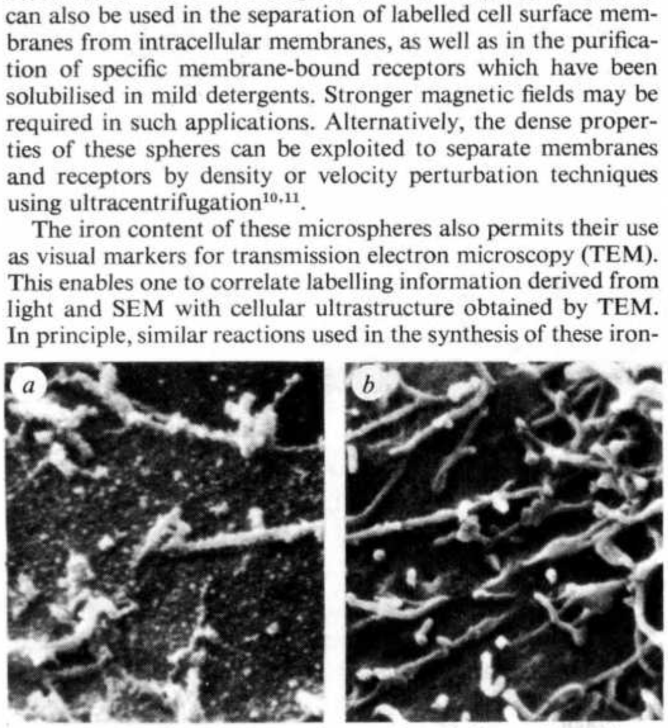

Fig. 2 Scanning electron micrographs of the surface of a cultured Hela cell labelled with fluorescein–Fe microsphere–WGA conjugates in *a*, the absence and *b*, the presence of the WGA inhibitor, *N*-acetyl chitobiose. Microspheres bind only when the inhibitor is absent during labelling.

Finally, these or related reagents may have future clinical applications. Magnetic microspheres carrying cytotoxic drugs, enzymes or radioisotopes could, in principle, be localised in a certain tissue of a body such as a tumour, by applying powerful magnets and serve as diagnostic or therapeutic agents.

Formation and resealing of pores of controlled sizes in human erythrocyte membrane

APPLICATION of an electric pulse, at field intensities of a few kV cm^{-1} and of duration in the μs range, to an isotonic suspension of erythrocytes is known to cause haemolysis of the red cells[1–4]. Studies from different laboratories suggest that the haemolysis is due to the field-induced transmembrane potential[1,3,4]. Our recent experiments[5] indicate that once the transmembrane potential reaches a threshold of approximately 1 V, which corresponds to an applied field of 2.2 kV cm^{-1}, the erythrocyte membrane becomes leaky to normally impermeant ions or molecules. The permeation of solutes leads to the swelling and eventual lysis of the red cells. This type of haemolysis is known as colloid osmotic haemolysis[6,7]. The voltage-induced permeability change is consistent with the formation of pores in the membrane. We show here that the size of these pores can be varied in a controlled manner, and that the leaky membrane can be resealed while the haemolysis is prevented. Foreign molecules have successfully been incorporated into the resealed, but otherwise intact, erythrocytes.

In the experiment shown in Fig. 1, erythrocytes in an isotonic NaCl solution were treated with a 3.7 kV cm^{-1}, 20-µs pulse, and the subsequent change in cell volume V was monitored by light scattering measurement. In these conditions, intracellular K$^+$ leaks out, being replaced with Na$^+$, within a few minutes. Further entry of NaCl causes the swelling of the red cells[5]. When V reached 1.1 V_0 (where V_0 is the volume of the untreated cells) a small amount of isotonic solution of various substances was added to the suspension (time $t = 0$). Curve *d* in Fig. 1 is a control, where 1/10 volume of isotonic NaCl was added. The cells kept swelling because of the continuous influx of NaCl. However, when the same amount of sucrose solution was added, the swelling immediately stopped as shown in curve *b*. A separate tracer experiment showed that the cell membrane is practically impermeable to sucrose in these conditions. Therefore, the above result indicates that the reduction of the external NaCl concentration by 9% is just sufficient to abolish the electrochemical gradient, or the resultant uptake, of NaCl. As expected, the addition of a larger amount of sucrose solution reduced the external NaCl concentration further, and the cells began to shrink due to the efflux of NaCl (curve *a*).

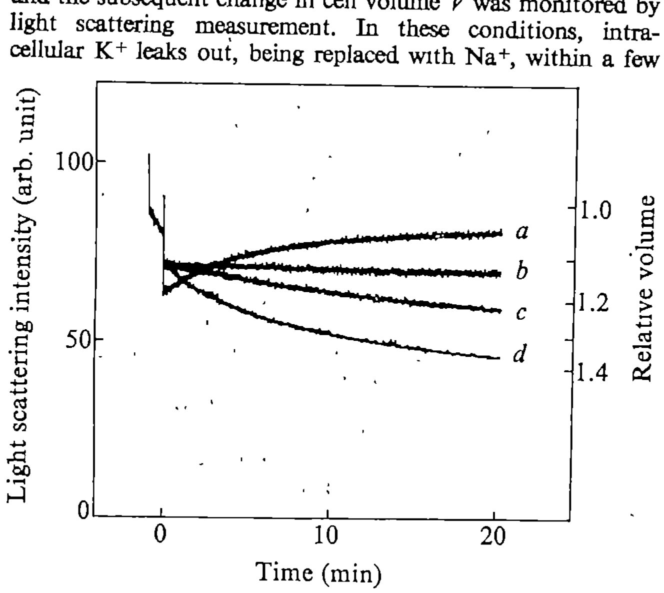

Fig. 1 Changes in cell volume after the electric pulsation. Washed human erythrocytes were suspended in an isotonic NaCl solution (150 mM NaCl, 7 mM phosphate buffer, *p*H 7 0) at a volume concentration of 1%, and treated with a single square-wave electric pulse of intensity 3.7 kV cm^{-1}, duration 20 µs, between a pair of stainless steel electrodes After 10–20 s, an aliquot was taken and mixed with 50 volumes of the isotonic NaCl solution, and the change in light scattering intensity at 600 nm was recorded with an Aminco–Bowman spectrofluorometer equipped with a magnetic stirrer. The scattering intensity was calibrated against the cell volume V by a separate haematocrit measurement, as shown in the right-hand scale which applies to the $t > 0$ portion of curves *b*–*d*. When V reached 1.1 times that of the untreated V_0, the following additions were made ($t = 0$). Curve *a*, 2/10 volume of isotonic (272 mM) sucrose solution to 1 volume of the suspension; curve *b*, 1/10 volume of the isotonic sucrose solution; curve *c*, 1/10 volume of isotonic (285 mM) xylitol solution; curve *d*, 1/10 volume of the isotonic NaCl solution. Temperature was 25 °C. In these conditions, the extent of haemolysis is negligible for the 20-min period shown; however, all the cells haemolyse by 15 h unless the carbohydrates are added.

When the added substance was xylitol (MW 152 whereas sucrose is 342), only partial blocking of the cell swelling was achieved as shown in curve *c*. The volume change in this situation is expected to satisfy the following relation

$$\mathrm{d}V/\mathrm{d}t = (j_x + j_{\mathrm{NaCl}})V/C \qquad (1)$$

where j_x and j_{NaCl} are the net influxes of xylitol and NaCl respectively, in mOsmol l^{-1} cells h^{-1} and C the total osmotic concentration of the medium in mOsmol l^{-1}. At $t \approx 0$ or $V \approx V_0$, the net influx j_{NaCl} is negligible, as shown in curve *b*, and the swelling is almost entirely due to the xylitol influx j_x. Thus the rate of permeation of xylitol molecule k_x can be roughly estimated as

$$k'_x \cong j_x/C_x = (V^{-1}\mathrm{d}V/\mathrm{d}t)_{t=0}(C/C_x) \qquad (2)$$

where C_x is the external osmotic concentration of xylitol ($C/C_x = 11$).

In this way, the permeability of the pulse-treated membrane to 11 different carbohydrates was measured in various conditions. (Tracer influx measurements on a few selected carbohydrates gave values consistent with those obtained by the above method.) The results are plotted in Fig. 2 against the average radius of the tested molecule. Curve *a* gives data for the untreated cells; molecules larger than erythritol do not enter the cells to any appreciable amount, except D-glucose which is known to be carried by a specific transport system[7]. This agrees with the idea that pores of a radius of about 3.5–4.2 Å exist in human erythrocyte membrane[8]. Curve *b* shows

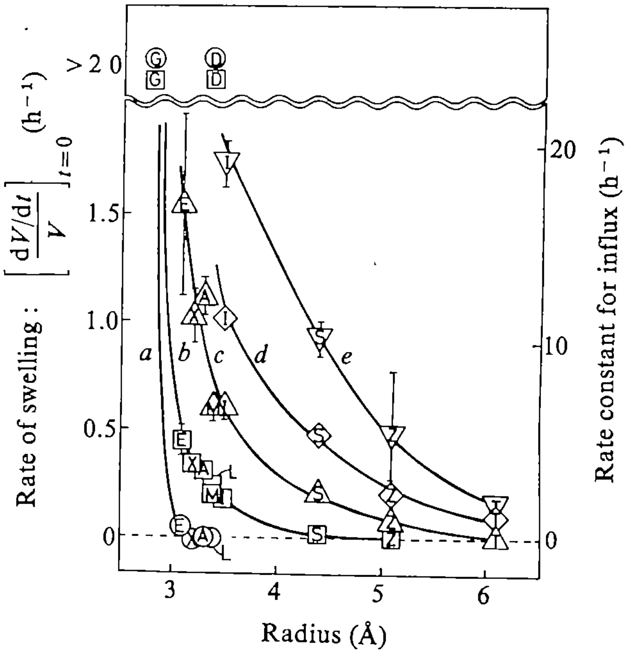

Fig. 2 Permeability of the pulse-treated erythrocyte membrane to various carbohydrate molecules. Curve *a*, untreated cells; curve *b*, cells treated with a 3.7 kV cm^{-1}, 20-µs pulse in isotonic NaCl solution; curve *c*, 5.3 kV cm^{-1}, 20-µs, in NaCl; curve *d*, 3.7 kV cm^{-1}, 80 µs, in NaCl; curve *e*, 3.7 kV cm^{-1}, 20 µs, in a 3:7 mixture of isotonic NaCl and isotonic sucrose solutions. After the pulsation, swelling of the cells due to the influx of various carbohydrate molecules was recorded as in curve *c* of Fig. 1 The rate of swelling was determined from the initial slope of the swelling curve; the rate of permeation was calculated from equation (2). The average radius in the abscissa denotes $(r_1 r_2 r_3)^{1/3}$ where the r_i values are three orthogonal radii measured in space-filling molecular models. G, glycerol; E, meso-erythritol; X, xylitol; A, D-arabitol; D, D-glucose; L, L-glucose; M, D-mannitol; I, myo-inositol; S, sucrose; Z, melezitose; T, stachyose.

Table 1 Incorporation of sucrose in resealed erythrocytes

Procedure		Assay					
Treatment	Medium	Time	% survival	Relative cell volume	Sucrose content (mmol l^{-1} cells)	Na^+ content (mmol l^{-1} cells)	K^+ content (mmol l^{-1} cells)
a Pulsation 3.7 kV cm^{-1}, 80 μs, 25 °C	NaCl 135 mM, NaP* 6 mM, sucrose 27 mM, *p*H 7.0	before *a*	100	1.00	0.0	91	10
b Resealing 1 37 °C, 1 h	NaCl 119 mM, NaP 7 mM, sucrose 27 mM, stachyose 21 mM, $MgSO_4$ 2 mM, *p*H 7.2	after *b*	99	0.99	3.2	92	11
c Resealing 2 37 °C, 6 h	NaCl 107 mM, KCl 5 mM, sucrose 27 mM, stachyose 21 mM, adenosine 3 mM, inosine 1 mM, supplement†, *p*H 7.5	after *c*	97	0.94	3.5	98	17
d Resealing 3 37 °C, 12 h	NaCl 107 mM, KCl 5 mM, $CaCl_2$ 2 mM, stachyose 40 mM, adenosine 0.3 mM, inosine 0.1 mM, supplement, *p*H 7.5	after *d*	95	1.01	3.2	81	27
e Test incubation 37 °C, 72 h	NaCl 133 mM, KCl 5 mM, $CaCl_2$ 2 mM, adenosine 0.15 mM, inosine 0.05 mM, supplement, *p*H 7.5	24 h in *e*	74	1.00	3.3	63	42
		48 h in *e*	65	0.99	3.3	55	46
		72 h in *e*	58	0.95	3.2	—	—

* NaP, Sodium phosphate buffer.

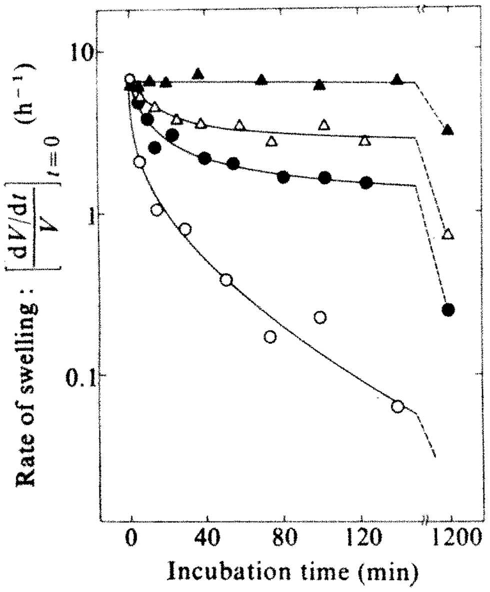
† Supplement: NaP 7 mM, $MgSO_4$ 2 mM, D-glucose 11 mM, chloramphenicol 0.1 mg ml^{-1}, penicillin G 500 units ml^{-1}, bovine serum albumin 30 mg ml^{-1}. Sucrose contained trace amount of [^{14}C] sucrose.

Volume concentration of the cells was ~ 20% at stage *a*, 10% at *b*, 3–5% at *c* through *e*. The suspension was gently rocked during the incubations. In *e*, medium was changed at every 12 h, during which *p*H dropped by 0.2–0.3 unit. Percentage survival was calculated from the amount of haemoglobin released in the supernatant. Relative cell volume was assumed to be inversely proportional to the amount of haemoglobin contained in a unit volume of packed cells (haemoglobin content of the untreated cells was 315±6 g l^{-1} cells). Sucrose content was determined from the radioactivity of the cells packed in microhaematocrit tubes. Na^+ and K^+ were assayed by flame photometry. Assay values except % survival refer to survived (unlysed) cells. All values are averages of several determinations on two independent samples; variations were within ±1% for % survival, ±0.02 for cell volume, ±0.2 mmol l^{-1} cells for sucrose, ±5 mEq l^{-1} cells for Na^+ and K^+.

that the treatment with a 3.7 kV cm^{-1}, 20, μs pulse increases the critical size for permeation: molecules smaller than sucrose can penetrate the membrane, and the rate decreases with the size of the molecule. Again, an exception to this curve is D-glucose; the specific transport system seems to be intact even after the pulse treatment. As can be seen from curves *c*, *d* and *e*, larger pores are obtained either by using a higher field intensity, by increasing the pulse duration, or by reducing the ionic strength of the pulsation medium.

As suggested by curve *b* in Fig. 1, addition of a sufficient amount of impermeant substance to the suspension of pulse-treated erythrocytes retards the haemolysis indefinitely. While the cells are prevented from lysis, the membrane spontaneously reseals as in the case of ghosts obtained by hypotonic lysis[9]. The resealing process is strongly temperature-dependent, as shown in Fig. 3. The ordinate is the rate of swelling measured in isotonic NaCl; as before, this rate is proportional to the net influx of NaCl. At 37 °C the treated membrane rapidly regains its impermeability to cations, whereas at 3 °C the cells remain highly permeable even after 20 h.

Fig. 3 Time courses of the resealing of pulse-treated erythrocytes at different temperatures. ▲, 3 °C; △, 17 °C; ●, 25 °C; ○, 37 °C. The washed erythrocytes in isotonic NaCl were treated with a 3.7 kV cm^{-1}, 80-μs pulse at 25 °C, and immediately mixed with a large volume of 85:15 mixture of isotonic NaCl and isotonic stachyose solutions kept at the specified temperatures. At intervals, an aliquot was taken and added to an isotonic NaCl solution of the same temperature, and the initial rate of swelling was measured as described in Fig. 1. Haemolysis in the incubation media (NaCl–stachyose) was negligible except at 3 °C, where a small portion of the cells haemolysed by 20 h presumably because of the very slow penetration of stachyose.



The electric pulsation followed by an appropriate resealing procedure makes it possible to prepare erythrocytes (not ghosts) with altered intracellular compositions. For example, the ionic composition of the resealed cells reflects that of the resealing medium: incubation in NaCl or KCl media yields cells loaded predominantly with Na^+ or K^+ respectively. Although the alteration of cellular cations can also be achieved by lactose treatment[10] or chemical modification of the cell membrane[11], the present method allows the incorporation of larger molecules such as sucrose by introducing pores of adequate size. Results of a typical experiment are shown in Table 1. The intactness of the loaded cells was tested by incubation for an additional 72 h in a simulated physiological medium at 37 °C. Although some haemolysis occurred, especially during the first 24 h of the test incubation, about 60% of the original cells survived the 3-d period. The cells in the medium assumed either normal biconcave or slightly cup-shaped disk forms and maintained approximately normal cell volume. The resealed erythrocytes accumulated K^+ and extruded Na^+ against a concentration gradient, indicating that the pores were almost completely annealed and the Na–K pump was intact.

At least two applications of the present technique are conceivable: (1) the alteration of intracellular compositions will simplify experimental designs, especially in transport studies. (2) Erythrocytes may be used as intravenous drug reservoirs; gradual release from loaded erythrocytes could help maintain the drug level in a patient's circulation.

Activation of mouse spleen cells by a single short pulse of mitogen

THE stimulation of lymphocytes by polyclonal mitogens such as concanavalin A (con A) is a useful system for analysing the activation of cells out of the resting state, G_0, into the division cycle. Optimal stimulation of the lymphocytes with con A, however, requires presence of the mitogen for about 20 h (ref. 1), and the cells transfer from G_0 into G_1 in an unsynchronised manner[2]. This lack of synchrony makes biochemical analysis of activation complicated because sequential events of the cell cycle become superimposed. I show here that a single short pulse of con A will irreversibly commit a significant proportion of murine spleen cells into the division cycle. This relatively synchronised stimulation of cells enables the requirements for activation to be analysed separately from subsequent events as the cells progress through the cell cycle. For example, it has been shown that the presence of colchicine during a 2-h exposure to con A inhibits mitogenic activation.

Spleen cells from 6–10-week-old male BALB/c mice were cultured in the absence of serum (Fig. 1 legend), and mitogenesis was measured by the incorporation of ^{3}H-thymidine into cellular DNA and the stimulation index (SI) calculated as c.p.m. con A-treated cultures/c.p.m. control cultures. Con A (1 μg ml^{-1}) was reduced to non-mitogenic levels after 3 h by changing the growth medium to remove free con A and adding 5 mM α-methyl-D-mannoside (α-MM) to displace cell-bound con A; this ratio of sugar to lectin (that is, 5 mM: 1 μg ml^{-1}) was used experimentally. The concentration of con A required for maximal mitogenic stimulation was dependent on the duration of exposure to the lectin (Fig. 1). Cells continuously exposed to con A gave a very sharp dose–response curve at 52 h which peaked at 1 μg ml^{-1} with SI = 252, and fell to background levels of DNA synthesis above 3 μg ml^{-1} con A. In contrast, identical cells given a 3-h pulse of con A showed a broad response curve peaking at 2–3 μg ml^{-1} at both 28 h and (SI = 25) and 52 h (SI = 183). This change in the dose–response curve is not a result of a change in the optimal dose requirements during the development of the mitogenic response, since the peak position was constant at both 28 h and 52 h following exposure to con A for either 3 h or 24 h (Fig. 1). It is relevant to note that when the dose–response curves were repeated in identical conditions, but using BALB/c thymocytes instead of spleen cells, 3-h exposure to con A did not produce a significant mitogenic response (maximal s.e. = 5.4 at 1.25μg ml^{-1} con A) although the same cells responded well after prolonged exposure to the lectin (Fig. 2).

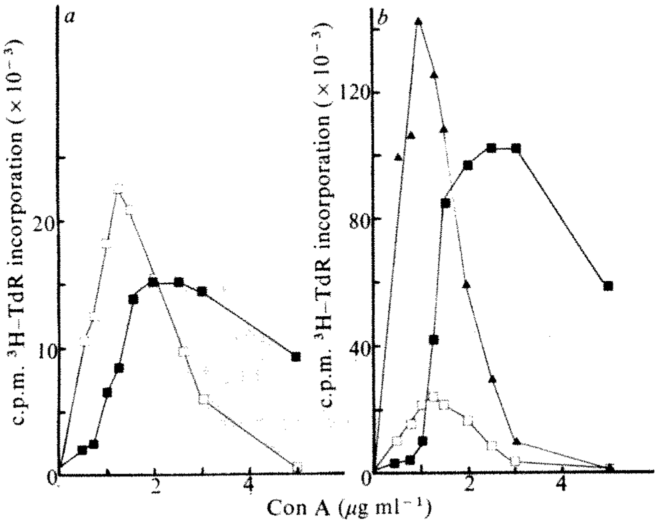

Fig. 1 Dose–response curves of BALB/c spleen cells to con A after 3-h, 28-h and 52-h exposure to the lectin. Labelling for *a*, 23–28 h; *b*, 47–52 h. Washed spleen cells from a single mouse were diluted to 5×10^6 ml^{-1} cells with growth medium (RPMI 1640 plus 100 U ml^{-1} penicillin and 100 μg ml^{-1} streptomycin) containing the required concentration of con A. Aliquots (100 μl) of these cells were dispensed into flat-bottomed wells of a microtitre tray and cultured in a humidified atmosphere of 10% CO_2, 7% O_2 and 83% N at 37 °C. Con A was removed by complete replacement of the supernatant with prewarmed growth medium containing the appropriate concentration of α-MM (see text). DNA synthesis was measured using standard techniques after labelling each culture with 0.5 μCi 6-^{3}H-thymidine (specific activity = 2.0 Ci mmol^{-1}) for 5 h. Each point represents the mean of 5 replicate cultures. ■, Con A 0–3 h; □, con A 0–28 h; ▲, con A 0–52 h. The same results were obtained in three separate experiments.

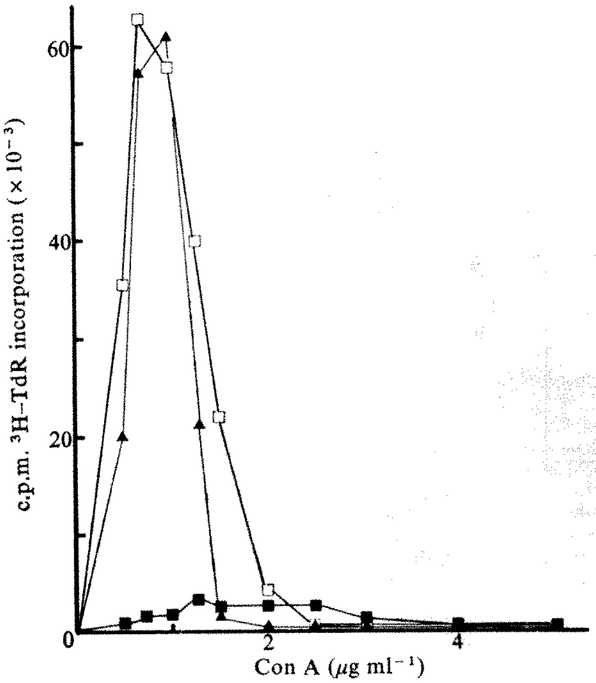

Fig. 2 Dose–response curves of BALB/c thymocytes to con A after 3 h, 28 h and 52 h exposure to the lectin. Experimental details as in the legend to Fig. 1. DNA synthesis was measured between 47–52 h. ■, Con A 0–3 h; □, con A 0–28 h; ▲, con A 0–52 h.

This time-dependent shift in the dose–response curve of spleen cells may be caused by a variety of cellular responses to con A which develop at different rates and show different sensitivity to the lectin. For example, concentrations of con A high enough to induce a complete activation signal in a short time may thereafter initiate an inhibitory effect dependent on prolonged exposure of the cells to con A. Lower concentrations of con A, although less effective during the inhibitory phase, require longer to generate a complete activation signal. A similar explanation has recently been suggested by McClain and Edelman[3]. On the other hand, the possibility that α-MM failed to reduce bound con A to non-mitogenic levels must be considered, although this is unlikely since addition of α-MM abolished

Table 1

Experiment no.	Time (h) 0 1 2 3	H^3-TdR incorporation (c.p.m.)	$b/a \times 100$
1 *a*		169+/−14	105%

5 *a*	←———con A———→	16,863+/− 724	26.8%
b	←———con A———→ ←—C—→	4,532+/− 322	

Murine spleen cells were cultured as described in the legend to Fig. 1. Cultures were exposed to 5 μg ml^{-1} con A and 0.5 μM colchicine (C) during the times indicated by the horizontal bars, and these agents were removed by complete replacement of the supernatant with prewarmed growth medium containing 25 mM α-MM. Controls were always treated identically to experimental cultures to ensure that the effect of medium change and sugar addition did not interfere with the results. ^{3}H-thymidine uptake was measured between 47–52 h and each value represents the mean of five cultures. In each experimental group *a* were the control cultures.

mitogenesis in control experiments. In addition, the different characteristics of cell populations responding to acute and prolonged exposure to con A (that is, the shape of the dose–response curves and duration of DNA synthesis) show that the α-MM did not cause a simple shift in the dose–response curve. Further confirmation of the efficacy of α-MM is apparent in the experiments with thymocytes, which responded well to prolonged exposure to con A but were unable to respond to a 3-h pulse.

These results are pertinent to the analysis of early cellular responses to con A which constitute an activation signal. Such analysis often uses con A concentrations which give maximal DNA synthesis at 48 h in the continuous presence of con A, but it is clear that this concentration of con A is insufficient to generate a significant activation signal within a short time. In contrast, short pulses of high concentrations of con A can activate cells within a few hours (Fig. 1). From these results it is suggested that in order to analyse the early events in the activation of cells from G_0 to G_1 it may be important to use a concentration of con A high enough to generate an activation signal within a short period.

The finding that lymphocytes will transform after a single short pulse of con A contrasts with results of Toyoshima *et al.*[4], who found that two 3-h pulses, separated by a gap of 12 h, are necessary for optimal con A stimulation (SI = 3.9) and that a single 3-h pulse did not induce DNA synthesis (SI = 1.2) in murine spleen cells. The discrepancy between this result and my own may be due partly to the presence of serum in the experiments of Toyoshima *et al.*, since their control cultures showed a high background of DNA synthesis presumably caused by the nonspecific mitogenic action of serum. In my cultures the absence of serum maintains the cells in a quiescent state but able to respond specifically to added mitogen, as indicated by the high stimulation indices of around 200.

Colchicine is known to bind tubulin and thereby reduce the microtubule system in cells. Its effect on lymphocyte mitogenesis in the continuous presence of con A has led to conflicting published results. For example, Betel and Martijnse[5] found that colchicine had no effect on the activation of rat lymphocytes by con A, but that the drug did block subsequent events in the cell cycle. In contrast, others[6] found that the inhibitory effect of colchicine was limited to the time of lymphocyte activation. In my own experiments using synchronously activated spleen cells, I found that short pulses of colchicine during the activation time caused a marked inhibition of mitogenesis (see Table 1). A 1-h pulse of colchicine immediately following con A treatment, however, had little effect on con A mitogenesis (Table 1). This supports the idea that colchicine inhibits events which are involved in the activation of cells. It was also found that the presence of colchicine during the final 24 h of a 52-h culture of cells (activated by a 2-h pulse of con A) caused marked inhibition of DNA synthesis measured at 47–52 h. These results suggest that an intact microtubular system is necessary for both mitogenic activation and the normal progression of the cell through the cell cycle.

Development of mast cells from grafted bone marrow cells in irradiated mice

BOTH basophilic granulocytes and tissue mast cells are known to have receptors for immunoglobulin E (IgE) and granules which contain histamine and heparin[1,2]. In spite of their similar physiological role, these two types of cells are thought to be independent cell lineages; the former are derived from the bone marrow, and the latter are connective tissue cells[2]. The differentiation of mast cells from their precursors, which were supposed to be undifferentiated mesenchymal cells, and the proliferation of these precursors were reported to occur in the skin of mice[3,4]. These results do not necessarily exclude the possibility that the precursor cells themselves are originated from the bone marrow, however. To examine such a possibility, we investigated whether mast cells of the donor origin appeared in radiation chimaeras, using the giant granules of beige (Chediak–Higashi syndrome) mouse[5] as a quantitative marker for mast cells. We have found that tissue mast cells can be derived from grafted bone marrow cells in irradiated mice.

Beige (C57BL-Bg^J/Bg^J) mice (Jackson Laboratory, Bar Harbor, Maine) and normal (C57BL−+/+) mice were bred in

Table 1 Appearance of donor-type mast cells in various tissues

Mouse no.	Time after transplantation (d)	% of donor-type mast cells Caecum	Mesentery	Skin	Glandular stomach	Forestomach
M12	9	0	0	0	0	0
M25	24	0	0	0	0	0
M28	42	9	0	0	6	0
M04	63	96	0	0	79	1
M01	96	78	2	0	66	5
M10	126	79	6	0	57	26
M26	152	98	11	14	87	46
M54	180	94	2	0	56	36

The appearance of mast cells with giant granules was monitored at various times after the transplantation of bone marrow cells of the beige mice into the irradiated normal mice. The method of transplantation was described previously[12].

our laboratory. At an age of 3 months, normal mice were irradiated (800 rad) and injected intravenously with bone marrow cells (5×10^6) of either beige or normal mice. On various days after the cell injection, a blood sample was obtained from a lateral tail vein of recipient mice. The mice were then killed; the caecum, the stomach and a piece of dorsal skin were removed and fixed in 10% buffered formalin (*p*H 7.2). The stretch preparation of the mesentery was also fixed in 10% formalin. Blood smears were fixed in formaldehyde vapour, stained with Sudan black B, and counterstained with Giemsa solution[6,7]. More than 100 neutrophils with distinctly segmented nuclei were counted. Tissues were embedded in paraffin; sections and the streched mesentery were stained with acidified toluidine blue[5]. In most cases, more than 200 mast cells were counted in each tissue.

Over 90% of neutrophils had giant granules after the 8th day of the cell injection, and were considered to be of donor origin.

Examination of tissues under the microscope revealed the following. (1) Most of mast cells in the caecum were of donor origin after the 63rd day of the cell injection (Table 1). (2) Most of mast cells in the mesentery and the skin were of host type even on the 180th day (Table 1). (3) In the glandular stomach, mast cells of the donor type were predominant, whereas those of the host type were superior in the forestomach which is covered with stratified squamous epithelium (Table 1). (4) No mast cells with giant granules were found in any of control mice which had received the marrow cells of the normal mice after irradiation.

Our results clearly shown that most of the mast cells under glandular epithelium are originated from the grafted marrow cells and that mast cells of the host remained predominant under squamous epithelium and in the mesentery. As mast cells constitute less than 0.01% of the nucleated cells in the bone marrow of C57BL mice (both Bg^J/Bg^J and +/+, unpublished), and as it takes about 40 d for the mast cells of the donor origin to appear, the donor-type mast cells found in various tissues seem to be derived from the precursor cells rather than from the mature mast cells contained in the marrow of the donor.

Two possibilities are postulated to explain the difference in the proportion of the donor-type mast cells in the various tissues. (1) Mast cells under glandular epithelium may be different from those of other tissues. Enerbäck found that granules of some mast cells in the intestinal canal of the rat were not fixed with 10% formalin[8]. Moreover, intestinal mast cells stained according to the method of Enerbäck decreased in nude mice[9], although mast cells of the skin increased in these mice[10,11]. As 10% formalin was used for fixation in the present experiment, the mast cells counted in the intestinal canal should be different from the "mucosal mast cells" of Enerbäck. (2) Mast cells in the various tissues are of the same kind, but the turnover rate of the cells is different in each tissue presumably because the differentiation from the precursor cells is locally controlled. Further investigation is in progress to see whether the cellular contact or chemical factor, which act only in the short range, have a major role for the differentiation of mast cells.

We thank Mr S. Fujihira and Mr T. Itahashi for making histological sections, Drs M. Seki and K. J. Mori for discussions and Professer K. Matsumoto for encouragement. This work was supported in part by the Japanese Ministry of Education, Science and Culture.

Evidence for Fc receptors on rabbit yolk sac endoderm

APPLICATION of the erythrocyte-antibody rosette technique (EA rosette) to cell cultures of mouse yolk sac membranes has provided evidence of Fc receptors on yolk sac endoderm of this species[1]. Binding of immunoglobulin (Ig) to Fc receptors forms an integral part of a hypothesis proposed by Brambell[2] to account for selective materno-foetal transmission of antibodies. In this hypothesis the receptor protects attached Ig when a transporting endocytotic vesicle (be it in syncytiotrophoblast, yolk sac endoderm, or gut enterocytes, according to the species) contacts proteolytic enzymes after fusion with lysosomes. Little is known about selective transport of antibodies across mouse yolk sac endoderm and it is not clear[1] to what extent these results show binding specific for transport of Ig across the endodermal cells, or merely reflect some special mechanism for endocytosing this particular class of proteins. Studies of rabbit yolk sac endoderm have not shown whether specific binding of Ig takes place; thus bovine IgG, which is poorly transported across rabbit yolk sac endoderm[3,4], although readily endocytosed[5], binds to the same extent as rabbit IgG to membrane components isolated from the cells[6]. On the other hand, compared with rabbit IgG, relatively little specific binding of bovine IgG was found when these proteins were incubated *in vitro* with formalin-fixed rabbit yolk sac[7]. We have now applied the EA rosette technique to rabbit yolk sac endoderm and find Fc receptors which bind both rabbit and human IgG, but not bovine IgG, pointing to their association with selective Ig transport.

To obtain yolk sac endodermal cells, conceptuses at 24–26 d of gestation were removed intact from pregnant Dutch or New Zealand White rabbits and washed free of contaminating blood with Hanks Balanced Salt Solution (BSS), *p*H 7.5. This was used free of calcium and magnesium to aid cell separation in subsequent procedures. Previous unpublished observations have shown that the exocoelomic fluid of the rabbit conceptus is rich in macrophages, as is the mesenchymal tissue of the paraplacental chorion[5]. In order to reduce possible contamination by macrophages and to provide a control population of Fc receptor positive cells, the exocoelomic fluid was removed by inserting a Pasteur pipette through a slit made in an avascular region of the chorion and flushing out the cavity with BSS. Flushing from different conceptuses were pooled. The yolk sac splanchnopleur was then dissected free of chorion, placed in a Petri dish with its endodermal surface uppermost and washed with BSS so as to remove blood issuing from the cut ends of vessels and macrophages possibly adhering to the exocoelomic mesothelium. BSS containing 0.5% trypsin and 10% foetal calf serum (FCS) was then added and incubation carried out at 37 °C for 1.5 h. The incubation medium was then carefully removed and fresh BSS/10% FCS pipetted on to the yolk sac endoderm so as to dislodge the cells. These were pooled from different conceptuses of the same rabbit and washed three times in a large volume of BSS/10% FCS. Between washings it was found necessary to pass cells through a hypodermic needle to achieve a single-cell suspension. Cells were finally suspended in Eagles Minimal Essential Medium containing 10% FCS and antibiotics at a concentration of 5×10^5 cells per ml.

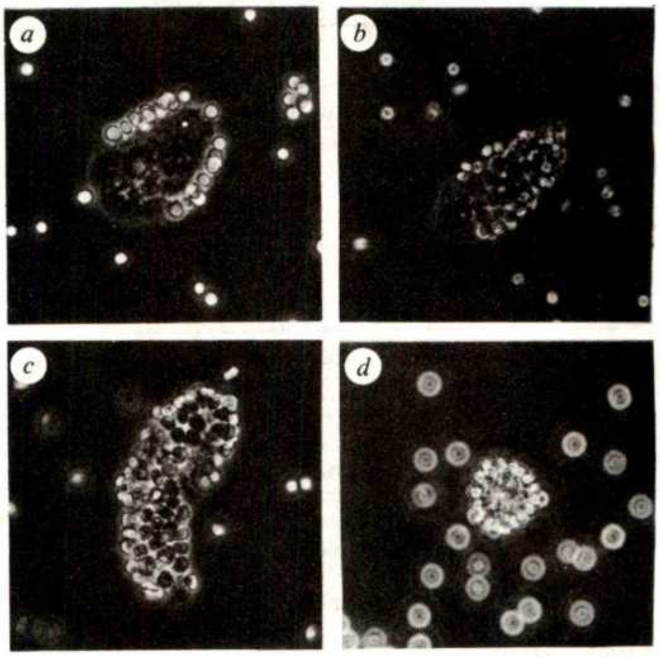

Fig. 1 Appearance of EA rosettes formed with yolk sac endodermal cells (*a*, *b* and *c*) and an exocoel macrophage (*d*). All photographs taken at the same initial magnification of ×298.

Table 1 Effect of rabbit antibody class and fragments on EA rosette formation with yolk sac endoderm (YSE) and exocoel macrophages (ExMac)

Fab	0	0	0	0	0	0	3.7	1.5	0
Control SRBC	0	0	0	0	0	0	3.5	4	0

NT, Not tested

*IgG, IgM, F(ab′)2 and Fab fractions derived from IgG were pure as defined by immunoelectrophoresis.

†Rosettes were formed by mixing equal volumes of YSE or ExMac and a 0.7% suspension of appropriately sensitised SRBC (tested for sensitisation with goat anti-rabbit immunoglobulins). Such mixtures were centrifuged at 150*g* for 3 min and the pellet gently resuspended. Aliquots were then mounted beneath coverslips on microscope slides and observed with ×40 phase objective. Cells showing at least five adherent SRBC were scored as positive. At least 100 cells were counted and the percentage of YSE or ExMac forming rosettes calculated. Duplicate samples normally showed agreement to within 5%.

A variable but significant number of rosettes were formed between yolk sac endodermal cells and sheep red blood cells (SRBC) coated with rabbit IgG; control SRBC and SRBC coated with IgM, and with F(ab′)2 or Fab fragments of IgG, did not form rosettes (Table 1). These results therefore show the presence of a receptor for the Fc region of rabbit IgG on at least a proportion of yolk sac endodermal cells; the variability observed is similar to that found for mouse yolk sac endoderm[1]. A very high percentage of exocoel macrophages also formed Fc dependent rosettes but we are confident these were not the source of rosetting cells in yolk sac endodermal cell preparations. By observing and counting rosettes under high power phase contrast microscopy, yolk sac endodermal cell rosettes could readily be distinguished from those formed by exocoel macrophages by their difference in morphology. Rosetting yolk sac endodermal cells frequently retained their columnar shape and sensitised SRBC were seen attached either in a band mainly at one pole (Fig. 1*a*) or distributed more widely over the cell surface (Fig. 1*b*, *c*). Exocoel macrophage rosettes differed by being smaller and very round in appearance with attached SRBC covering the cell surface (Fig. 1*d*). Several factors could have influenced the proportion and also the type of rosetting yolk sac endodermal cells observed. Although there may well be genuine differences between endodermal cells with respect to whether or not they possess Fc receptors, receptor sites might also have been blocked on some cells by endogenous IgG present within the uterine lumen; such IgG might be differentially released by the action of trypsin. Longer exposures of yolk sac splanchnopleur to trypsin-containing incubation medium did not have any consistent effect on the percentage of yolk sac endodermal rosettes subsequently scored, but it has been reported that treatment of formalin-fixed yolk sac splanchnopleur with trypsin reduces subsequent specific rabbit IgG binding by about 75% (ref. 8). Movement of receptors at some stage after isolation of cells from what is normally a polarised epithelium, might explain why attachment of sensitised SRBC occurs at sites other than what may be construed as the apical cell surface. But, no increase in the number of cells with SRBC attached more widely over the cell surface was seen when cell suspensions were further incubated after initial rosette counts. In an alternative mechanism to that proposed by Brambell, it has been suggested[9] that the receptor functions not so as to protect immunoglobulin from proteolysis within phagolysomes, but rather to segregate, at the cell surface, immunoglobulin destined for transport and that destined for proteolysis. It was envisaged that the receptor became associated with a distinct class of transporting coated micropinocytotic vesicles and subsequent studies[10] have detected rabbit and human IgG, but not bovine IgG, in coated vesicles in confluence with the lateral and basal plasmalemma. Thus endodermal cells engaged in transporting IgG may normally have free receptors generated at sites other than the apical cell surface as a result of coated vesicles fusing with the plasma membrane and these might account for the wide distribution of attached SRBC.

Rabbit, human and bovine IgG solutions were tested at two different protein concentrations for their ability to inhibit attachment of rabbit IgG sensitised SRBC to yolk sac endodermal cells. Rabbit and human Ig were most effective in this respect, but little or no inhibition occurred with bovine Ig (Table 2). Human IgG and rabbit IgG Fc were also very effective in inhibiting attachment but human IgM and rabbit IgG Fab had very much less, and in some cases, no effect. Rabbit albumin was also ineffective; indeed for some unknown reason this consistently enhanced the number of yolk sac endodermal cells forming rosettes with sensitised SRBC. These results thus confirm the importance of the Fc region of IgG for attachment to receptors on yolk sac endoderm. They also indicate that rabbit and human IgG bind to the same Fc receptor but that little if any binding of bovine IgG, human IgM or rabbit serum albumin occurs to this same receptor. The possibility does of course exist that separate receptors are present for these non-competing proteins, but that this is not the case for bovine IgG was shown by immunising a cow with SRBC and sensitising the SRBC with antibodies present in whole serum or the IgG fraction of this serum. As can be seen from Table 3, bovine IgG sensitised SRBC, unlike rabbit IgG sensitised SRBC, do not form rosettes with yolk sac endodermal cells. This could not be attributed to lack of a comparable degree of sensitisation, since exocoel macrophages showed a similar high level of rosette formation in parallel studies carried out with bovine or rabbit IgG sensitised SRBC. As mentioned above, bovine IgG is not transported across yolk sac endoderm to any significant extent, although it is readily endocytosed. Rabbit and human IgG are more readily transported across rabbit yolk sac endoderm and all three immunoglobulins can be detected in phagolysosomes[11]. Since there is no apparent binding of bovine IgG to an Fc receptor, the inescapable conclusion seems to be that there is an association between the Fc receptor and selective immunoglobulin transport. Clearly, yolk sac endodermal cells, in view of their difference in binding affinity for bovine IgG, must have subtle differences in the nature of the Fc receptor compared with that present on macrophages. The presence of Fc receptors specific for IgG has also been demonstrated on human syncytiotrophoblast, both by EA rosette formation[12] and immune cytoadherence[13]. Also, binding of IgG to the human placental receptor seems to be dependent on an intact Fc region since neither C2 or C3 homology regions would competitively inhibit binding of IgG (ref. 14). This is again different to the macrophage Fc receptor, which will bind the isolated C 3 homology region[15].

Table 2 Inhibition of YSE–EA rosette formation by homologous and heterologous proteins

Protein tested* (mg ml^{-1})		Mean % inhibition†	Range	No. of animals
Rabbit Ig				
0.5		78.5	68.0–83.3	4
5.0		95.0	90.0–100	3
Human Ig				
0.5		93.4	91.1–95.4	4
5.0		100	100 –100	3
Bovine Ig				
0.5		14	0.0–28.0	4
5.0		(–)3.0	(–)14.3–17.1	3
Human IgG		85.9	83.1–88.7	2
Human IgM	all at	6.8	0.0–13.6	2
Rabbit IgG Fc	0.5 mg ml^{-1}	71.4	60.2–78.5	3
Rabbit IgG Fab	final conc.	2.0	(–)35.5–30.0	3
Rabbit albumin		(–)6.2	(–)2.2–(–)11.5	3

YSE cells were mixed with equal volumes of protein solution and left at room temperature for 30 min before adding equal volumes of either sensitised or control SRBC. Rosettes were then enumerated as described in Table 1. All tests carried out with control SRBC were negative in these experiments.

*Human and bovine Ig were obtained from Koch-Light (Cohn Fr. 2) and rabbit Ig from Calbiochem; they were principally IgG.

† % Inhibition = 100 – (% rosettes formed between IgG sensitised SRBC and YSE in presence of competing protein/% rosettes formed in absence of competing protein × 100).

Table 3 Effect of rabbit and bovine IgG sensitising antibody on EA rosette formation with yolk sac endoderm (YSE) and exocoel macrophages (ExMac)

Source of sensitising antibody to SRBC	Mean % rosettes* for YSE and range	Mean % rosettes* for ExMac and range	No. of animals
Rabbit whole serum	11.8 (8.0–19.0)	97.0 (94.0–100)	4
Rabbit IgG fraction	26.3 (16.0–45.5)	81.6 (52.0–96.5)	6
Bovine whole serum	0 (0)	56.2 (25.0–100)	4
Bovine IgG fraction	0.2 (0–1.0)	75.8 (50.0–96.0)	6
Control SRBC	0.2 (0–2.0)	3.5 (0–11.0)	10

*Determined as described in Table 1.

We thank Professor G. T. Stevenson and Dr E. V. Elliott (Tenovus Laboratory, Southampton General Hospital) for supplying immunoglobulins and rabbit anti-SRBC antibody fragments, and the MRC for financial support.

Localisation of gonadotropin-releasing hormone in the circumventricular organs of human brain

Gonadotropin-releasing hormone (GnRH) and thyrotropin-releasing hormone (TRH) are two hypothalamic oligopeptides which regulate the secretion of gonadotropins and thyrotropin, respectively, from the anterior pituitary[1,2]. It is generally accepted that these neurohormones are produced by nerve cells, transmitted along axons and stored in nerve endings. When released, they are transferred by way of the hypothalamo–hypophyseal portal system to the anterior pituitary[3]. We have recently reported[4] that in the human hypothalamus most of the GnRH is found in the preoptic area while TRH is localised mainly in the posterior nucleus. Exceedingly high concentrations of the two neurohormones were found in the pituitary stalk. The localisation of the two neurohormones in distinctive regions of the hypothalamus and pituitary stalk may represent sites of synthesis in neuronal cell bodies and storage in nerve terminals, respectively. It has recently been found[5] that significant amounts of GnRH are present in the circumventricular organs (CVO) of the rat brain. These organs consist of specialised ependymal cells, small nerve cells and axon terminals containing small dense core vesicles. The axon terminals end on fenestrated capillaries comprising many capillary loops[6]. Such an anatomical arrangement is characteristic of neurohumoral secretion, and is present also in the human pituitary stalk[7]. In this study we have determined, by radioimmunoassay, the distribution of GnRH and of TRH in the circumventricular organs of the human brain. We report that exceedingly high concentrations of GnRH, but not of TRH, are present in one of the circumventricular organs, the organum vasculosum of the lamina terminalis (OVLT), and discuss the possible physiological function of this structure in the neural control of reproduction.

Different brain structures were removed during routine autopsies carried out at the Institute of Forensic Medicine, Tel Aviv. The tissues were obtained from six females, 19–70 yr old, and from four 30–70-yr-old males, seven of them killed in road accidents and three suicide cases. The bodies were kept for 4–52 h at 4 °C until autopsy. Identical storage conditions did not affect GnRH or TRH content of brain tissue[4]. The circumventricular organs (Fig. 1) and the tissues surrounding them were removed under a dissecting microscope and sectioned into several blocks. The pituitary stalk and specific hypothalamic regions were sectioned as described previously[4]. Each of the segments (52 tissue blocks per brain) was extracted and analysed for GnRH and TRH by radioimmunoassay, as described previously[8,9]. Protein determination was performed according to the Lowry method[10]. The pineal body, a circumventricular organ, was excluded from this study since we have previously shown that it does not contain any significant amount of GnRH or TRH (ref. 4).

The largest amount of GnRH and TRH was found in the pituitary stalk (52ng of GnRH and 21 ng of TRH). A considerable amount, however, of GnRH (9.4 ng) was also found in the OVLT (Table 1); its concentration in this structure (36.4 ng per mg protein), exceeded even that found in the pituitary stalk (20.7 ng per mg protein). The lamina terminalis surrounding the vascular structure, as well as the other CVO, contained negligible amounts of GnRH. Relatively low concentrations of TRH were found in all the CVO (Table 1). Within this limited series, neither the amount and concentration of GnRH in the OVLT and pituitary stalk, nor the distribution of the neurohormone between these two organs could be shown to be related to age or sex of the subjects.

It seems likely that in the human, the OVLT, like the pituitary stalk, functions as a neurosecretory organ: the specific localisation and high concentration of GnRH in both organs, and the presence of a rich vasculature, and of nerve endings terminating on capillary loops, would suggest neurohumoral secretion of the hormone at these two sites. The physiological significance of GnRH secretion at the pituitary stalk is well established: the hormone is carried by way of the hypothalamo–hypophyseal portal system to the anterior pituitary, thereby inducing gonadotropin release. The role of GnRH originating in the OVLT is not clear. Transport of the hormone to the anterior pituitary by the circuitous route of the cerebrospinal fluid or by the general circulation seems unlikely. Alternatively, the drainage of the OVLT towards the preoptic area in the human[11] could provide a pathway for distribution of GnRH to diverse brain regions. In these areas, the hormone could modulate neurotransmittory functions or influence the activity of different neurones.

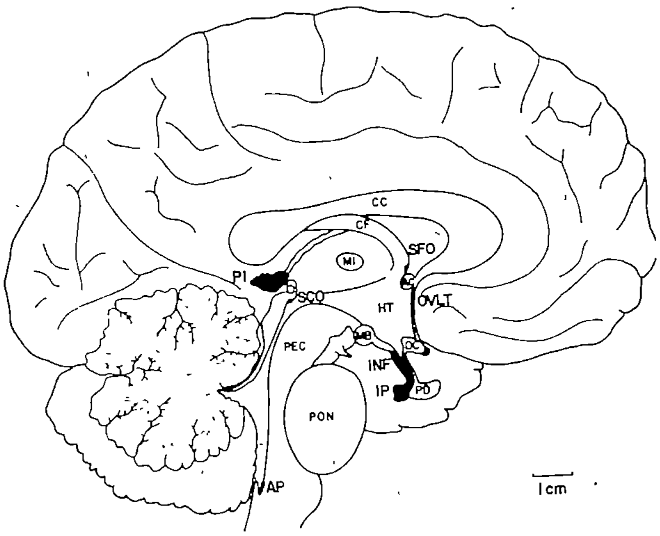

Fig. 1 The circumventricular organs of the human brain (in black), in a midsagittal plane section. AP, area postrema; INF, infundibulum of neurohypophysis (pituitary stalk); IP, infundibular process of neurohypophysis (posterior pituitary); OVLT, organum vasculosum lamina terminalis; PI, pineal body; SCO subcommissural organ; SFO, subfornical organ. Other structures: AC, anterior commissure; CC, corpus callosum; CF, column of fornix; Ht, hypothalamus (shaded area); MB, mammillary body; MI, massa intermedia; OC, optic chiasma; PD, pars distalis of adenohypophysis; PEC, peduncle of cerebrum; PON, pons.

Several observations suggest a possible relationship between the OVLT and behavioural and endocrine parameters of sexual function. Destruction of the preoptic area, to which the OVLT is adjacent, modifies sexual behaviour in several animal species[12] and disrupts the female oestrous cycle of the rat[13]. Wenger[14] has recently shown a correlation between the endocrine state of the female rat and the number of dense core vesicles in the OVLT resembling those of the GnRH-containing vesicles of the median eminence of the hypothalamus. Moreover, a direct effect of GnRH on sexual behaviour has been demonstrated by Moss and McCann[15] and by Pfaff[16], who by administration of GnRH to ovariectomised or ovariectomised hypophysectomised rats were able to induce mating behaviour.

While in the rat brain considerable concentrations of GnRH were found in all the CVO (ref. 5), the human brain

contains high concentrations of GnRH in the pituitary stalk and OVLT only. The basic anatomical resemblance of the OVLT and the pituitary stalk suggests that GnRH is secreted from the vascular organ as well. It is possible that the GnRH secreted from the OVLT may have a role in the regulation of the menstrual cycle and sexual behaviour. However, further work is required to establish the exact physiological role of GnRH localised in the OVLT.

Chemical carcinogens stimulate canine kidney (MDCK) cells to produce prostaglandins

WHILE investigating the regulation of prostaglandin production by cells, I found that the MDCK line from dog kidney[1] responds to treatment with several polycyclic aromatic hydrocarbon carcinogens, aflatoxin B_1 and 1,2,7,8-diepoxyoctane. Metabolic activation of the hydrocarbons was required for this stimulation of prostaglandin production.

The MDCK cell line, which morphologically resembles epithelium, was obtained from Dr Charles D. Stiles, University of California, San Diego. Exponentially growing cells were incubated in Eagle's minimal essential medium containing 2 mM *l*-glutamate and supplemented with 10% (v/v) foetal bovine serum and penicillin–streptomycin. Duplicate dishes were used for each reagent and each experiment was repeated at least once. The values obtained for prostaglandins per cell were similar for each reagent in all experiments. Media were assayed for PGE_2 and $PGF_{2\alpha}$ with either anti-PGE_2 or anti-$PGF_{2\alpha}$: anti-$PGF_{2\alpha}$ reacts 0.1% with PGE_2 and the anti-PGE_2 reacts 0.01% with $PGF_{2\alpha}$. (The antisera do not identify the prostaglandins as either monoenoic or dienoic.)

MDCK cells produce prostaglandins—about eight times more $PGF_{2\alpha}$ than PGE_2. When the cells were incubated in the presence of benzo(*a*)pyrene (0.1 μg ml^{-1}), the content of $PGF_{2\alpha}$ and PGE_2 in the medium increased. In my experiments the production of prostaglandins by MDCK cells and its stimulation in the presence of benzo(*a*)pyrene depended on cell density. At all densities, however, the cells produced greater levels of prostaglandins in the presence of benzo(*a*)pyrene (0.1 μg ml^{-1}).

When cells were plated at 2×10^5 per dish, stimulation by benzo(*a*)pyrene (0.1 μg ml^{-1}) was observed after 48 h of incubation. Benzo(*a*)pyrene was not required throughout the 48 h. There was equivalent stimulation if cells were incubated at 2×10^5 per dish for 24 h with benzo(*a*)pyrene, washed twice and incubated for a further 24 h in medium lacking benzo(*a*)pyrene. This procedure therefore was used to test the various reagents. Medium from the second 24-h incubation was assayed for serological activity with anti-$PGF_{2\alpha}$ and anti-PGE_2.

Table 1 shows that the cells incubated with the most active polycyclic aromatic carcinogens[2-6] produced the highest levels of prostaglandins. Incubation with benzo(*a*)pyrene at 0.5 μg ml^{-1} stimulated prostaglandin production 13-fold and at 0.2 μg ml^{-1}, 5–5.5-fold. Among the fungal toxins tested, only the most potent carcinogen, aflatoxin B_1 (ref. 5), at 0.05 and 0.02 μg ml^{-1}, stimulated prostaglandin production, while the weakly active carcinogenic aflatoxins, at 0.1 μg ml^{-1}, did not. Neither the aromatic amines nor the nitrosamines, at 0.5 μg ml^{-1}, affected prostaglandin production.

The direct-acting carcinogen, 1,2,7,8-diepoxyoctane, at 0.5 μg ml^{-1}, stimulated prostaglandin production 3–3.5-fold. The 1.7-fold stimulation due to chrysene (0.5 μg ml^{-1}) was statistically significant (0.533 ± 0.05 fg of PGE_2 per cell (medium) and 0.903 ± 0.19 fg per cell (chrysene) $P < 0.005$; and 2.92 ± 0.26 fg $PGF_{2\alpha}$ per cell (medium) and 4.93 ± 0.48 fg per cell (chrysene) $P < 0.005$).

Several polycyclic aromatic hydrocarbons stimulated prostaglandin production. Metabolism of these compounds to arene oxide products by enzymes such as aryl hydrocarbon hydroxylases are required for carcinogenic activity[6,7]. Such metabolism can be blocked by 7,8-benzoflavone[8,9]. 7,8-Benzoflavone inhibited stimulation by benzo(*a*)pyrene, 7,12-dimethylbenz(*a*)anthracene and aflatoxin B_1, but not that of 1,2,7,8-diepoxyoctane; 7,8-benzoflavone, on the other hand, increased stimulation by the latter (Table 2). The inhibitors of microsomal monoxygenases, SKF 525-A and metyrapone[10] (0.1 μg ml^{-1}) inhibited stimulation by both benzo(*a*)pyrene and 1,2,7,8-diepoxyoctane by 20%; while 1,2-epoxy 3,3,3-trichloropropane (1.0 μg ml^{-1}), an inhibitor of epoxide hydrase, had no effect.

Table 2 Inhibition by 7,8-benzoflavone of stimulation of prostaglandin production in MDCK cells by benzo(*a*)pyrene

Effector	μg ml^{-1}	$PGF_{2\alpha}$ (fg per cell)	Increase in prostaglandin production*
No addition	—	3.9	1.0
7,8-Benzoflavone	0.1	3.6	0.9
7,8-Benzoflavone	0.01	3.7	0.9
7,8-Benzoflavone	0.001	3.8	1.0
Benzo(*a*)pyrene	0.1	16.7	4.3

1,2,7,8-Diepoxyoctane	0.5	11.7	3.0
+7,8-Benzoflavone	0.1	19.9	5.1

*Expressed as relative to level found in medium alone (1.0); for example, a value of 4.3 represents a 4.3-fold increase in prostaglandin production.

After incubation with the carcinogens that stimulated prostaglandin production, trypsin-treated MDCK cells were larger than either trypsin-treated control cell or cells incubated with non-stimulating reagents. No attempt, however, was made quantitatively to correlate this increase in cell size with increased prostaglandin production.

Greater prostaglandin production by transformed cell lines than by their parent cell lines has been reported[12,13]. Methylcholanthrene-transformed mouse fibroblasts produce more prostaglandins because their synthetase activity is higher[13]. Stimulation of the activity of the microsomal enzyme complex prostaglandin synthetase could also account for the stimulation reported here. On the other hand, increased synthetase activity may reflect the morphological changes in the cells, with no induction of enzyme. Increased phospholipase activity, either as a result of induction of phospholipases or as a consequence of the morphological alterations, could also account for the stimulated prostaglandin production by increasing the availability of arachidonic acid, the substrate for prostaglandin synthetase.

Human fibroblasts (D550), rabbit endothelial cells (CLO) and mouse fibroblasts (3T3), although they produce prostaglandins, were unaffected by benzo(*a*)pyrene (0.2 μg ml^{-1}; 48 h incubation). MDCK cells probably contain the metabolic enzymes necessary to convert the procarcinogens to prostaglandin-stimulating compounds, but they do not seem to have those required to activate aromatic amines or nitrosamines to stimulators of prostaglandin production; other cell lines which may have these enzymes are being studied. The relationship of carcinogenicity to stimulation of prostaglandin production at the concentrations used is positive (Table 1). With increased concentrations of some of the reagents (5 μg ml^{-1} and above), the false negatives may be positive. But toxicity becomes marked at higher levels and a procedure to quantify the contributions of the toxic and non-toxic effects to prostaglandin production is being developed. The MDCK cell line may prove to be a sensitive indicator of the carcinogenic potential of the hydrocarbons.

I thank Elaine Powers, Louanna King and Jon Masor for technical assistance, Dr Aviv Hassid for helpful discussions and the NCI for support.

Infectious primate type-C virus shed by healthy gibbons

MANY captive gibbons are naturally exposed to infectious type-C virus based on the prevalence of animals with humoral antibodies reactive to the virus[1,2] and isolation of virus from tissue of leukaemic[3,4] and normal gibbons[5]. A closely related infectious type-C virus has also been isolated from a woolly monkey with a spontaneous fibrosarcoma[6,7] which implies that a common virus could infect unrelated non-human primates. Several reports recently have identified infectious primate type-C virus[8,9], viral components[10] and humoral antibody reactive to this virus in leukaemic[11] and normal humans[12] suggesting that man also may be susceptible to infection by a related virus. In an attempt to identify a possible source for infectious primate type-C virus that might infect primates as well as other animals, we decided to investigate whether healthy captive gibbons were shedding viruss ince this non-human primate is frequently displayed at zoos or kept as pets. This report presents evidence that gibbons can have long term viraemia with type-C virus without detectable immune response. These viraemic animals actively shed infectious virus in urine and faeces.

Blood samples were taken monthly or when available from laboratory, pet and zoo gibbons (*Hylobates* sp.) for clinical, virological and serological studies. All gibbons under observation were initially free of any clinical symptoms. Blood samples (3–5 ml) were taken from the femoral vein for plasma and sera. Plasma was used to infect virus-susceptible cell cultures. Serum samples were used to detect the presence of humoral antibody.

Faecal and urine specimens were collected during the monthly physical examination. Each urine specimen was filtered through a 0.45 μm Millipore filter then concentrated by differential centrifugation. The sterile concentrate was resuspended in physiological buffered saline (PBS) and used as an inoculum. Each faecal sample was initially diluted as a 20% suspension in PBS. The suspension was subjected to low speed centrifugation to remove the large particles. The clarified suspension was filtered through a 0.45 μm Millipore filter, then subjected to high speed centrifugation to pellet the virus. The pellet was resuspended in PBS and used for inoculum.

Fifty-three gibbons were examined over 12 months for the presence of infectious type-C virus and viral-specific humoral antibody. All gibbons were separated into two major groups depending on whether the animals were or were not exposed to the virus. Animals in group 1 were considered normal, that is, free of detectable infectious virus and humoral antibody. Animals in group 2 were those animals which had been exposed to type-C virus as determined by either the presence of infectious virus or humoral antibody. Results are summarised on Table 1. Thirty-three of the 53 gibbons (62%) examined were considered normal. Two hundred and ten plasma samples from these animals lacked evidence for the presence of infectious virus and humoral antibody. None of these animals seroconverted during the study period.

Animals in group 2 were divided into two subgroups based on whether the animal had detectable humoral antibody or infectious viraemia. Two hundred and twenty-two blood samples from 14 antibody positive gibbons were examined for humoral antibody and virus. All the samples from subgroup A contained humoral antibody but none of the samples contained detectable infectious virus. The humoral antibody titre for viral envelope antigen in these animals generally ranged from 1/4 to 1/16 by IFA except for one animal which ranged from 1/32 to 1/128. The radioimmune precipitation assay for P_{30} ranged from 1/50 to 1/490 (ref. 14). Many of these animals were examined on several later occasions and in no instance did any of them convert from antibody positive to detectable viraemia. Tests on 38 samples from six viraemic gibbons (subgroup B), however, showed that all the samples contained infectious type-C virus but lacked detectable humoral antibody. One viraemic gibbon has been observed for over 4 yr and some have been observed for at least 1 yr. Four of the six gibbons are still under observation, two died after 6 and 12 month observations. One animal developed maligant leukaemia–lymphoma while the other died of unknown cause. All the remaining gibbons continue to be in good health.

Table 1 Gibbon antibody and virus detection

Group	Animals	Antibody	Virus
1 Normal	33	0/210	0/210
2 Virus-infected			
A Antibody-positive	14	220/220	0/210
B Antibody-negative	6	0/38	38/38

Detection of virus was performed by infecting the susceptible human lymphoid cell culture (NC-37) with the prepared inoculum. Approximately 2×10^6 viable cells were concentrated into a pellet and resuspended in 0.2 ml of inoculum. The suspension was agitated for 90 min and then fresh medium was added to each tube. After three passages (1:3) the virus was concentrated from the tissue culture supernatant and assayed for viral DNA-polymerase in the presence of oligo dT·poly rA[3]. Viable cells were examined for viral envelope antigen by direct immunofluorescence (IFA) as previously described[4]. All positive cell cultures were confirmed for replicating type C virions by electron microscopy[3].

Antibody reactive to type-C virus in gibbon sera was determined by indirect immunofluorescence assay (IFA) using viable infected and non-infected gibbon and human lymphoid cells as targets. The secondary antibody was FITC conjugated goat antihuman IgG or anti-monkey IgG as previously described[1].

Isolation of virus from viraemic gibbons was consistent which suggested that these animals probably had a high virus titre. In order to determine the approximate titre in the plasma, infectious virus was titrated by the endpoint dilution method. Results in Table 2 indicate that most gibbons had high virus titre. One animal (HLA-21), which was examined many times, showed a constant titre between 10^1 and 10^2 infectious virus (IV) ml^{-1}. These results indicate that viraemic gibbons can tolerate a very high virus titre without any overt ill effects.

Since infectious type-C virus could be consistently isolated from the blood of these viraemic gibbons, we examined urine and faecal samples from these animals to determine if infectious virus was being excreted which could serve as a possible source for dissemination of the agent. Results are summarised in Table 2. Infectious virus could be readily isolated from fresh urine and intermittently from faecal samples of viraemic gibbons. Isolation of infectious virus from excretory products seems to depend on the virus titre of the viraemic animals. None of the normal nor antibody-positive gibbons was found to excrete detectable levels of infectious virus in their urine or faeces.

The present study clearly indicates that healthy gibbons can have persistent type-C virus infection and can shed infectious virus. Gibbons must be highly susceptible to type-C infection in order to account for the prevalence of the virus found in this species. In most instances, the animal developed an active immunity probably resulting from low grade chronic multiplication of the virus in the tissues. A few animals with high level virus multiplication developed long term viraemia without detectable humoral antibody response, possibly because of partial immunological tolerance for the virus or because the virus multiplication exceeded the antibody response in the host. This situation may be similar to cats infected with feline leukaemia virus (FeLV) where the infected cats lack diseases or detectable immune response[15].

Table 2 Comparison of viraemia and detection of virus in urine and faeces

Animal no.	Age (yr)	Health	Virus	Detection of infectious virus	
			IV ml^{-1}	Urine	Faeces
HLA-21	6	normal	10^{1-2}	1/6	0/3
HLA-30	6	malignant leukaemia–lymphoma	10^4	ND	ND
HLA-68	3.5	normal	10^5	10/14	4/14
HLA-71	9	normal	10^5	14/16	10/16
HLA-72	2	normal	10^5	2/5	4/5
4 AB pos	4–6	normal	0	0/64	0/70

The gibbon virus is essentially identical to the woolly monkey fibrosarcoma virus[16,17] which has been demonstrated to be oncogenic in marmosets[18] and has characteristics in common with other known animal oncornaviruses. Based on molecular hybridisation analysis the infectious primate virus is exogenous to the species[19,20] and probably transmitted horizontally. The mode of transmission may be similar to FeLV[21]. While several investigators have reported detection or isolation of infectious primate type-C virus[8,9] and humoral antibody reactive to the agent in normal and leukaemic humans[11,12], other investigators were unable to confirm these findings[21]. This controversial point requires further study and needs to be resolved. Although there is no evidence that the gibbon agent is infectious to man, it is known that many non-human primate agents can infect man[23]. More importantly, this study indicates that there are gibbons which seem to be in good health in zoo and pet environment which are shedding infectious type-C virus and may be a source for dissemination of this virus. Four gibbons in this study were from such an environment and were essentially normal in their behaviour as far as appetite and activity. Routine clinical and physical examination of these animals showed no discernible abnormalities and only with specific immunological tests was the infection detected. One gibbon developed malignant leukaemia–lymphoma during this study which suggests the oncogenicity of this agent. The other viraemic gibbons may develop similar disease, however, at present they continue to be healthy and active. Further studies are needed to determine whether the gibbon agent is infectious and oncogenic to other primates.

This study was conducted under Contract NOI-CP-3-3242 with the Virus Cancer Program of the National Cancer Institute, National Institutes of Health, PHS.

Spatial summation and light adaptation in the goldfish visual system

IN attempting to explain how visual acuity improves as illumination increases, Pirenne and Denton[1] suggested that the retinal image is sampled by numerous units, each summing the effects of light over a region of the retina. At very low luminances, only units with the largest summation areas are functional, but with increasing luminance smaller units come into play as their thresholds are exceeded. Since that suggestion was made, cells at all levels of the visual system have been studied electrophysiologically and many receptive fields have been described that might form the basis for such units. Goldfish and other cyprinid fishes, have been the subjects of many such studies, and their retinal synaptic connections have been revealed in detail. I report here some psychophysical experiments which show the effects of light adaptation on spatial summation in the goldfish. The results are consistent with the connections made by rods and cones in the cyprinid retina, and with the theory of a progressive recruitment of ganglion cells with smaller receptive field centres as background luminance is raised.

Radiance thresholds of goldfish (12 cm standard length) were measured by classical conditioning of respiration[2]. Each fish was restrained with its body parallel to a diffusing screen at 14 cm from the left eye. The test stimuli were disks of monochromatic light (533 nm) projected for 5 s in the centre of the fish's visual field. The animals were trained by giving a brief electric shock at the offset of the test stimulus so that the shock-elicited inhibition of breathing came to be evoked by the light stimulus. The occurrence of a response was judged by a 4-alternative forced choice procedure: the test stimulus was presented randomly in one of four 5-s periods within each minute. A response was counted if the stimulus period contained an interbreath interval longer than those in the other three periods. Thresholds were estimated from a staircase tracking procedure[3].

Figure 1 shows how threshold radiance changes with stimulus diameter when dark adapted (*a*), and against an adapting tungsten-light background of 3.4 mL (*b*). When light flux is summed perfectly, sensitivity (1/threshold) increases in proportion to stimulus area (Ricco's Law) up to the limit of full summation, and thereafter increases no further. Since the data can be fitted by two straight line segments, one of slope 2, representing Ricco's Law, and one of zero slope, the limit of full summation can be conveniently expressed by the 'critical diameter' (CD) at which the two lines intersect.

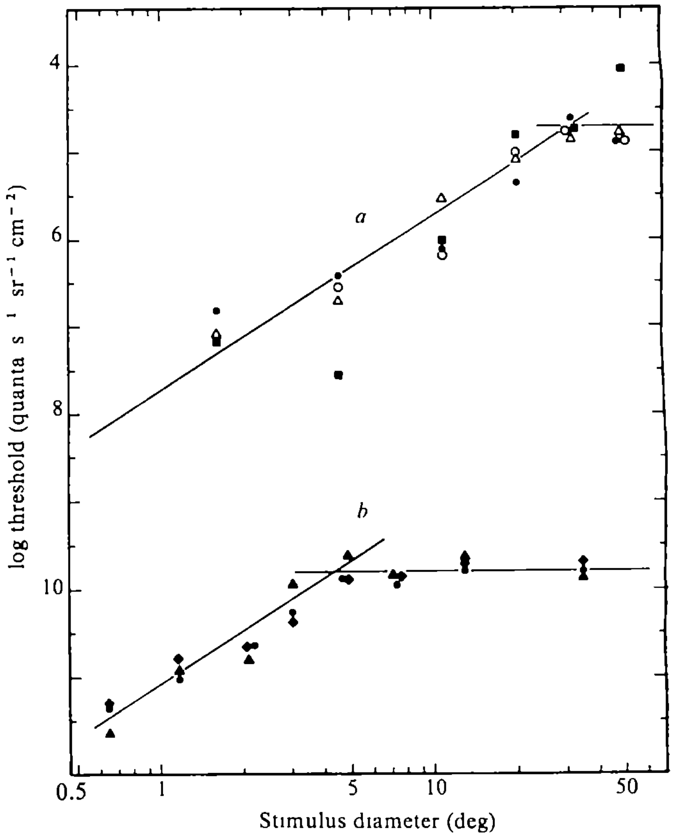

Fig. 1 Threshold stimulus radiance of wavelength 533 nm as a function of stimulus diameter at two different adaptation levels. Each symbol represents data from a different fish. The sloping lines show a reciprocal relationship between threshold and stimulus area (Ricco's Law). Lines fitted to data by eye. *a*, Thresholds obtained after at least 30 min of dark adaptation; *b*, thresholds to test stimuli projected on a tungsten-light background (3,000 K) of 3.4 mL.

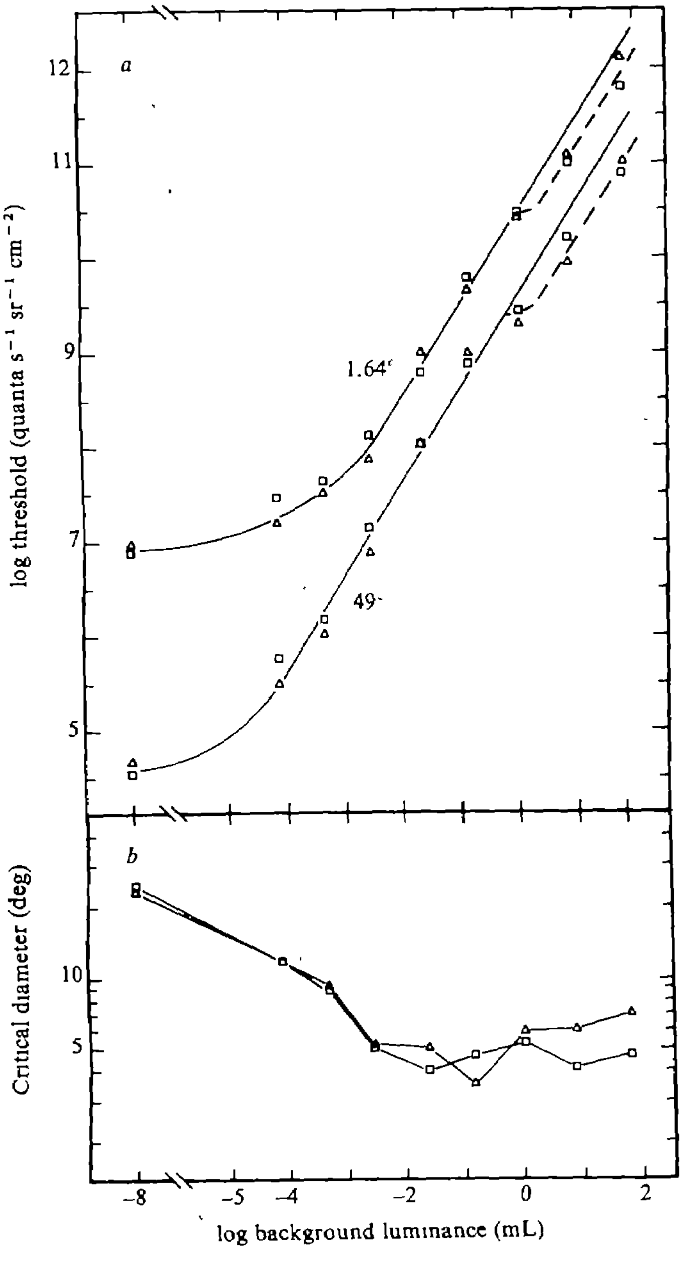
In the dark-adapted state, full summation takes place for stimuli subtending up to about 30° of visual angle. With a 49° diameter stimulus, the mean absolute threshold of four goldfish in terms of stimulus radiance was 58,200 quanta s^{-1} sr^{-1} cm^{-2}, which is 38% of the human absolute threshold measured in similar conditions[4]. Using targets of more than 100°, goldfish thresholds fell to about 15% of the human value, indicating some partial summation above 30°. Very similar absolute thresholds to large stimuli have previously been obtained for goldfish[5].

To examine how sensitivity and spatial summation vary with the state of adaptation, thresholds in two goldfish to a small (1.64°) and large (49°) stimulus superimposed on different luminances of tungsten-light background were measured. Figure 2*a* shows that backgrounds have the usual desensitising effects: threshold rises at an increasing rate until it changes in proportion to background luminance (Weber's Law) as shown by the straight lines. At a background luminance of ~1 mL however, this linear relationship is interrupted by what seems to be a rod-cone break. A previous psychophysical study on goldfish found a similar break at about the same adaptation level[6].

Given that straight lines of slope 2 and 0 describe the threshold-diameter data (Fig. 1), CD can be estimated from the intersection of two such lines drawn through the 1.64° and 49° stimuli respectively. Thus CDs at different background luminances (Fig. 2*b*) were derived from the corresponding pairs of thresholds in Fig. 2*a*. CD in these two goldfish fell from a dark-adapted value of 25° to about 5° in a fairly continuous fashion, remaining essentially constant above 3×10^{-3} mL. In humans, however, CD falls with increasing background luminance in two distinct phases: first to an intermediate level while the rods determine threshold, and then to a lower level when the cones take over[7]. The fact that the goldfish CD falls without interruption, in spite of the break in the threshold–background luminance function, suggests that rod and cone signals are pooled over similar retinal areas. An equality of spatial summation in the rod and cone systems of goldfish, and the lack of it in humans can possibly be explained by the retinal organisation of the two species. In mammals, the bipolar cells contacted by rods are different from those contacted by cones[8], but in cyprinid fishes, several types of bipolar cell are contacted by both rods and cones[9,10]. Furthermore, these fish bipolar cells receive their rod and cone input from the same retinal area, presumably leading to equal rod and cone summation areas at the bipolar and subsequent levels of processing.

Fig. 2 *a*, Threshold stimulus radiance as a function of background luminance for 533-nm test disks of 1.64° and 49° diameter. △, And □, are data points from two goldfish of 12 cm standard length. The straight lines show Weber's Law and the dashed curves represent probable cone thresholds; *b*, relationship between critical diameter and background luminance. Each critical diameter (CD) in degrees of visual angle is found from the corresponding pair of thresholds (I_{49} and $I_{1.64}$) in *a* from $\mathrm{CD} = 1.64(I_{49}/I_{1.64})^{1/2}$.



It is unlikely that the spatial summation seen behaviourally in the goldfish could take place much before the retinal ganglion cells. As yet there is little physiological evidence for inter-receptor coupling in fishes as a basis for summation[11], although contacts between receptors have been found[10,12]. Anatomical and electrophysiological studies in cyprinid fishes show that the receptive fields of bipolar cells are smaller than the smallest behavioural critical diameters, being 2.5° in diameter at most[9,10,13], whereas the receptive fields of the laterally spreading elements, the horizontal and amacrine cells, are too large to account for the relatively small, light-adapted critical diameter[14,15]. Receptive field centres of ganglion cells are, however, found in a range of sizes that matches quite closely the range of critical diameters encountered at different adaptation levels. For the size of eye used in these behavioural experiments, the largest receptive field centres found by recording from retina or optic nerve would subtend about 30° of visual angle[16,17], although fields as large or larger that may belong to ganglion cells, are also found in the optic tectum[18,19]. When ganglion cells are recorded in the optic nerve or tectum with the fish's eye under water, the diameters of the smallest field centres are found by different workers to be between 3° and 5° (refs 19–22).

The correspondence between the range of diameters of receptive field centres and critical diameters suggests not only a summing role for ganglion cells, but also that critical diameters in the light and dark are determined respectively by the smallest and largest field centres. To explain this, first assume that the fish responds when one or more ganglion cells signal a significant change in light stimulation. In the fully dark-adapted eye, the largest fields should be the most sensitive for large test stimuli, since they are most likely to catch the minimum number of quanta s^{-1} required for detection. Critical diameter will then be set by the size of these fields. As background luminance is increased, the largest fields will catch more quanta from the background and will, as a result, be more desensitised than smaller fields. This phenomenon has been seen in cat ganglion cells[23]. Critical diameter will then be determined by progressively smaller field centres until, at a background luminance of about 3×10^{-3} mL and above, the smallest fields (3–5° in diameter) will determine the critical diameter. Such a mechanism may be the basis for the recruitment of smaller summing units proposed to account for the improvement of acuity with increasing luminance[1,23].

This work was supported by a DIMER Fellowship and Equipment Grant. I thank Dr A. M. Granda for his encouragement and the use of many of his facilities, including a PDP 11/10 computer.

Stability of Met-enkephalin content in brain structures of morphine-dependent or foot shock-stressed rats

THE discovery of enkephalin has suggested one more theory to explain the mechanisms of opiate tolerance and addiction. Kosterlitz and Hughes[1] proposed that a reduced enkephalin release might explain tolerance and physical dependence to opiates. Simantov and Snyder[2] supported this view by showing that the content of enkephalin was changed in brain of morphine-dependent rats. Others[3-5] have reported that Met-enkephalin is rapidly metabolised by brain tissue. Because of this *in vivo* lability of Met-enkephalin, particular precaution must be taken in the preparation of brain tissue samples for enkephalin assay. In fact, we have shown that by killing the rats with a microwave beam focused to the head and by taking particular precautions in preparing the brain samples we could measure Met-enkephalin concentrations which were higher (by several orders of magnitude) than the concentrations measured by other authors who failed to take such precautions[6]. Since the changes in the brain enkephalin content reported to occur either after a stress induced by foot shock[7] or during morphine dependence[2], were measured by a binding assay which lacks specificity for enkephalin, we decided to repeat these experiments with a technique that specifically measures Met-enkephalin[6] to decide whether the brain enkephalin content changes during stress[7] or opiate dependence[2].

We duplicated the technique described by Simantov and Snyder[2] to cause morphine dependence and withdrawal, the only deviation from their experimental design being the use of naltrexone 15 μmol kg^{-1} instead of naloxone 1 mg kg^{-1} to elicit morphine withdrawal.

To measure the Met-enkephalin content, male, Sprague–Dawley rats were killed with focused microwave irradiation[8] and the striatum and hypothalamus were dissected as outlined by Glowinski and Iversen[9]. The brain regions were extracted with 0.1 M acetic acid and the extracts neutralised with 1 M NaOH. The assay was carried out in polypropylene tubes. Non-labelled peptide or brain extracts were incubated with antiserum and ^{3}H-enkephalin in 0.5 ml, 0.2 M Tris buffer, *p*H 7.4, containing 0.1% albumin and 0.06% dextran. The ^{3}H-enkephalin bound to antibody was separated from the free ^{3}H-enkephalin by 0.2 ml 1.5% charcoal slurry containing 0.15% dextran and 0.9% NaCl. The supernatant was counted in a Beckman LS 250 liquid scintillation spectrometer. The method of preparation and the specificity of our antibody was as described previously[6].

Table 1 Morphine dependence and withdrawal on the content of Met-enkephalin in various brain structures

Treatment	Met-enkephalin (ng mg^{-1} protein) Hypothalamus	Striatum	Remainder of brain§
Control	2.6±0.9	5.0±1.0	1.0±0.14
Morphine*	3.1±1.5	6.2±2.9	0.91±0.20
Naltrexone†	3.8±0.9	6.3±1.1	0.93±0.15
Morphine‡ and naltrexone	2.8±0.9	7.0±1.5	0.78±0.14

Each value refers to the mean ± s.e.m. of the average of five determinations. The values were not corrected for recovery.

*One morphine pellet prepared according to Gibson and Tingstadt[10] was implanted. After 2 d, two more pellets (75 mg each) were implanted together. Rats were killed with microwave radiation 5 d after implantation of the first pellet.

†Naive rats were injected intraperitoneally with naltrexone 15 μmol kg^{-1} and killed with microwave irradiation 1 h later.

‡Rats were treated as in *, with the exception that naltrexone 15 μmol kg^{-1} was injected 1 h before microwave irradiation and brain extraction.

§The remainder of brain did not contain cerebellum.

As shown in Table 1, naltrexone, implantation of morphine pellets and the combination of the two treatments, failed to change the enkephalin content of various brain regions. The data reported in Table 2 show that after 60 min of intermittent inescapable foot shock administered exactly as described by Akil *et al.*[7] and Madden *et al.*[11], there was no change in the Met-enkephalin content of striatum, hypothalamus or the remainder of brain tissue.

Table 2 Inescapable foot shock on content of Met-enkephalin in various structures

Treatment	Met-enkephalin (ng mg^{-1} protein) Striatum	Hypothalamus	Remainder of brain
Control	8.8±0.6	3.6±0.7	0.43±0.09
Foot shock*	8.1±0.3	2.8±0.3	0.44±0.03

Each value refers to the mean ± s.e.m. of an average of six determinations.

*Foot shock consisted of 60 min intermittent inescapable foot shock (3 mA, 1 s duration, 1 per 5 s). Rats were killed with the microwave radiation immediately after shock.

Our data do not negate the possibility that in conditions of opiate dependence and withdrawal or after unavoidable foot shock, there is change in the concentration of an opiate receptor agonist of the endorphin type. Since our method measures specifically Met-enkephalin, our results merely negate that the brain content of this peptide changes during dependence. It was suggested that this increase in enkephalin was a biochemical reflection of the inactivity of enkephalinergic neurones[2]. It was argued that these neurones had ceased firing when the opiate receptor was occupied by saturating concentrations of morphine. We do not oppose the view that a feedback message links the occupancy of opiate receptors with the rate of firing of enkephalinergic neurones. Our results just indicate that the biochemical signal associated with the cessation of activities in enkephalinergic neurones is not an increase in brain enkephalin content. Perhaps changes in the synthesis rates of the enkephalin have a regulatory role for enkephalin steady state when neuronal activity changes. This possibility is in agreement with the finding that following the injection of naltrexone, the abrupt cessation of opiate receptor occupancy by morphine is not associated with a change in the steady state of Met-enkephalin. In contrast with reports by Akil *et al.*[7] and Madden *et al.*[11], we failed to find an increase in enkephalin content after stress elicited with considerable foot shock. This failure may be due to the more precise methodology that is now possible in comparison with early methods[2,7] or could be due to the fact that the method used by Simantov and Snyder[2] and Akil *et al.*[7] also measured β-endorphin which, during stress, may be mobilised from pituitary and accumulates in brain tissue. Since our method is specific for Met-enkephalin, we failed to detect a possible increase in brain β-endorphin content.

Comparison of specificity of agonist and antagonist radioligand binding to β adrenergic receptors

DIRECT radioligand binding methods have been used extensively to identify and characterise a wide range of hormone, drug and neurotransmitter receptors. Among the most intensively studied have been the β adrenergic receptors which mediate stimulation of the enzyme adenylate cyclase by catecholamines[1]. Until recently all of the successful binding studies of β adrenergic receptors have been performed with specific high affinity β adrenergic antagonists such as (−) ^{3}H-dihydroalprenolol[2], (±) ^{3}H-propranolol[3] or (±) ^{125}I-hydroxybenzylpindolol[4]. Earlier attempts to use radioligand β adrenergic agonists were generally frustrated by a great deal of nonspecific (that is non-receptor) binding[5]. We have developed a high affinity radiolabelled β adrenergic agonist, ^{3}H-hydroxybenzylisoprenaline, which, when used in conjunction with high concentrations of catechol and ascorbic acid which block non-receptor binding sites, seems to be a useful ligand for studying the β-adrenergic receptors[6]. We present here the results of parallel studies of agonist (^{3}H-hydroxybenzylisoprenaline, HBI) and antagonist (^{3}H-dihydroalprenolol, DHA) binding to β-adrenergic receptors in frog erythrocyte membranes. The ability of sixteen β-adrenergic agents (agonists and antagonists) to competitively inhibit binding of the two ligands in identical assay conditions (including catechol and ascorbate) has been compared. The results suggest an impressive coincidence of the binding data obtained with the two radioligands. These results are in contrast with those recently described for several central nervous system neurotransmitter receptors where it seems to be possible to identify discrete 'agonist' and 'antagonist' conformations of the receptors by performing binding studies with either a radiolabelled agonist or antagonist respectively[7–11].

The sources of all materials used have been reported previously[6,12]. The frog erythrocyte membrane preparation used in these studies was that previously described[13] and was obtained by centrifuging crude frog erythrocyte lysates over a cushion of 50% sucrose at 2,000*g* for 10 min. The membranous material which does not sediment through the sucrose was collected and used in all binding studies. These preparations have a five-to tenfold enhancement of β-receptor binding and adenylate cyclase activity as compared with crude lysates[13]. Binding assays with both radioligands were carried out essentially as before[6,14].

EC$_{50}$ values (concentrations of agents causing 50% displacement of specific binding) for any agent were determined in the same experiment using both radioligands. Five concentrations of each agent were generally tested. We have previously demonstrated that binding of both radioligands reaches steady state within the 10 min incubations at 37 °C (refs 6, 15). Dissociation constants (K_D) of various competing agents were not calculated since such calculations require an estimate of the K_D of the radioligands. We have previously demonstrated that ^{3}H-HBI binding is only slowly reversible and hence Scatchard[16] and similar analyses do not provide meaningful estimates of its affinity for the β receptors.

The ability of the (−) and (+) stereoisomers of propranolol to inhibit the binding of the two radioligands to frog erythrocyte membranes is depicted in Fig. 1*a*. It can be observed that the two sets of curves are virtually superimposable. The result is typical of the displacement curves obtained when β-adrenergic antagonists were used to inhibit radioligand binding

The ability of β-adrenergic agonists to inhibit the binding of the two radioligands is depicted in Fig. 1*b*. These results are typical of the displacement curves obtained with agonists. For potent agonists, such as (±)HBI, the displacement curve for (±)^{3}H-HBI was usually slightly (one-to twofold) to the left of that for (−)^{3}H-DHA. For weak agonists, however, such as (+)adrenaline, the curve for inhibition of (±)^{3}H-HBI was displaced somewhat more to the left of that for (−)^{3}H-DHA (in this case approximately threefold).

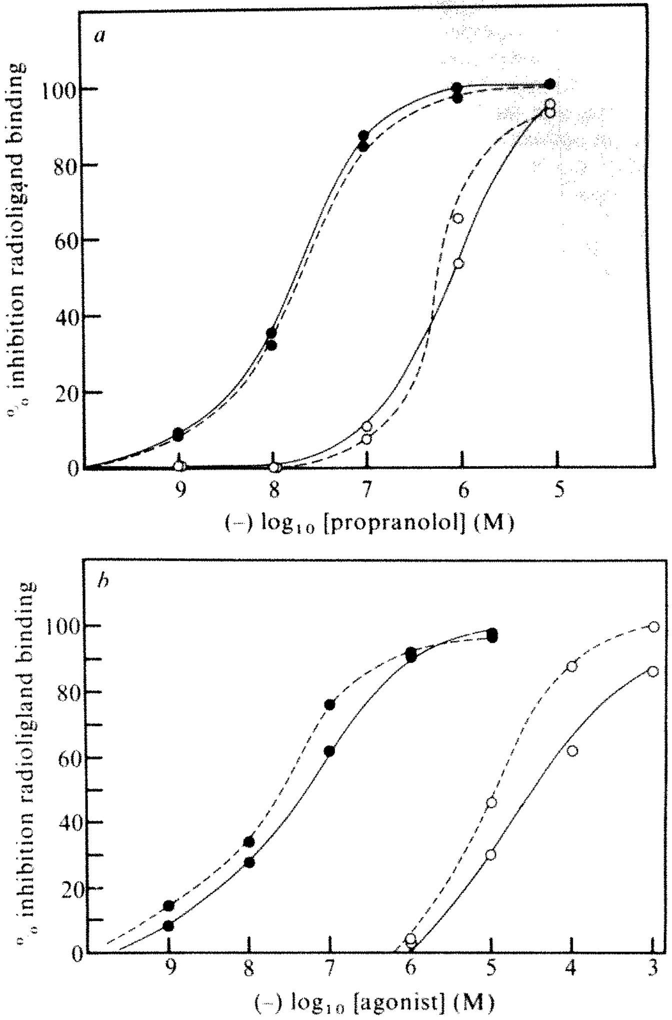

Fig. 1 *a*, Inhibition of radioligand binding to frog erythrocyte membrane β-adrenergic receptors by stereoisomers of propranolol. Membranes were incubated in a final assay volume of 150 μl which contained Tris-HCl, 50 mM (*p*H 7.5), 15 mM MgCl$_2$ and 40,000–50,000 c.p.m. (10 nM) (±)^{3}H-HBI (broken line) or ~ 60,000 c.p.m. (~ 10 nM) (−)^{3}H-DHA (solid line) in the presence or absence of various concentrations of adrenergic agents (—) propranolol (●) and (+) propranolol (○). All assays with either radioligand also contained catechol 3×10^{-4} M and ascorbic acid, 8×10^{-4} M to block non-receptor binding sites which might bind the labelled agonist. All incubations were performed for 10 min at 37 °C and were terminated by vacuum filtration through a Whatman GFC glass fibre filter followed by washing with either 10 ml (^{3}H-DHA) or 20 ml (^{3}H-HBI) of ice cold incubation buffer. Filters were dried overnight then counted in a triton–toluene based fluor in a Packard liquid scintillation spectrometer at an efficiency of 40%. Separate incubations were also carried out in the presence of 10^{-5} M (±)propranolol to determine 'nonspecific' binding. Specific or β-receptor binding in all cases was taken as total minus nonspecific binding. In separate experiments we demonstrated that these washing procedures reduced nonspecific binding while having no effect on specific binding[6,12]. At the radioligand concentrations used in these studies 'specific' binding was routinely ~ 70% of total binding with (±)^{3}H-HBI and ~ 95% of total binding with (−)^{3}H-DHA. Results shown are the means of three experiments. *b*, Inhibition of radioligand binding to frog erythrocyte membrane β-adrenergic receptors by a potent and a weak agonist. Results shown are the means of two or three experiments. Broken line, (±)^{3}H-HBI; solid line, (−)^{3}H-DHA. ●, (±)HBI; ○, (+)adrenaline.

A summary of EC_{50} values for the 16 adrenergic agonists used in this study as inhibitors of ^{3}H-HBI and ^{3}H-DHA binding is presented in Fig. 2 and Table 1. As shown in Fig. 2, the correlation between the two sets of data is excellent. When EC_{50} values for all antagonists for ^{3}H-HBI binding were compared with those for ^{3}H-DHA binding no statistically significant difference was found (paired t test, $P > 0.4$). For agonists, however, there was a significant difference ($P < 0.05$).

It may be noted that some of the EC_{50} values obtained in the present studies, especially those for catecholamine agonists are somewhat lower than values obtained previously[12]. This is apparently due to the protective effect of the catechol and ascorbate in the incubations on these agents and underscores the importance of comparing ^{3}H-HBI and ^{3}H-DHA EC_{50} values in identical experimental conditions.

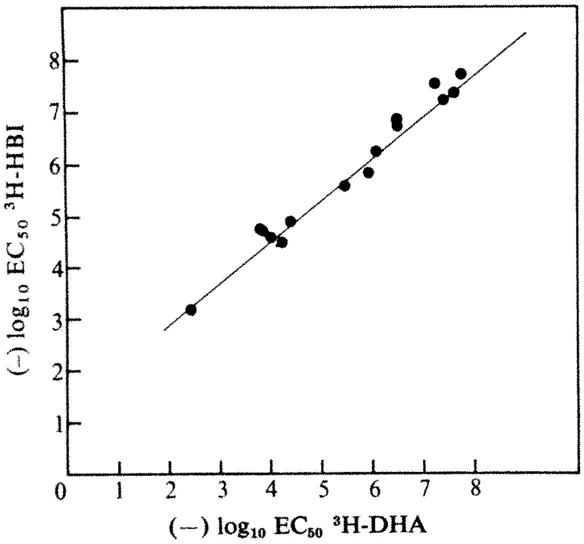

Fig. 2 Correlation of EC_{50} values for β-adrenergic agents determined by inhibition of $(-)^3$H-DHA and $(\pm)^3$H-HBI binding to frog erythrocyte membranes. The line was determined by linear regression analysis. $r = 0.99$.

Table 1 EC_{50} values for β-adrenergic agents determined by inhibition of (−) ^{3}H-dihydroalprenolol and (±) ^{3}H-hydroxybenzylisoprenaline binding to frog erythrocyte membranes

Agent	n	EC_{50} (nM)	
Antagonists		$(-)^3$H-DHA	$(\pm)^3$H-HBI
(−)Propranolol	3	0.018	0.020
(+)Propranolol	3	0.800	0.600
(−)Alprenolol	3	0.025	0.045
(±)Dichlorisoprenaline	3	1.2	1.5
(±)Phenylephrine	2	60	35
Dopamine	2	4,000	700
Agonists and partial agonists			
(±)Hydroxybenzylisoprenaline	3	0.060	0.030
(±)MJ 9184–1	2	0.044	0.060
(−)Isoprenaline	3	0.340	0.180
(−)Soterenol	3	0.320	0.150
(−)Adrenaline	2	3.5	2.5
(−)Noradrenaline	2	100	28
(+)Isoprenaline	2	150	20
(+)Adrenaline	2	42	13
(+)Noradrenaline	2	>1,000	380
(±)Cobefrin	3	150	18

n, Number of experiments determined in duplicate. Inhibition curves were plotted as shown in Fig. 1a and b for all agents for the determination of EC_{50} values.

The widespread distribution of β-adrenergic receptors in mammalian and non-mammalian species, their close relationship with the enzyme adenylate cyclase and the availability of several radiolabelled β-adrenergic antagonist ligands has served to focus a great deal of experimental effort on the β-adrenergic receptors in the past several years[15]. In a number of respects these receptors seem to serve as a prototype of adenylate cyclase-coupled receptors. Unlike the situation with receptors for several polypeptide hormones, there are a wide variety of both agonist and antagonist agents whose interactions with the β receptors can be studied. Until recently, however, only β-adrenergic antagonist radioligands had been successfully used for direct binding studies of these receptors. With the development of $(\pm)^3$H-HBI (ref. 6) it has become possible, for the first time, to perform parallel studies of an adenylate cyclase-coupled receptor with both a radiolabelled agonist and antagonist. As noted above, such studies are of particular interest in view of recent reports that for several central nervous system neurotransmitter receptors, discrete 'agonist' and 'antagonist' states of the receptors can be identified with such radioligands[7–11]. In such studies it has generally been found that agonists have considerably higher affinity (one to three orders of magnitude) for the sites labelled with the radiolabelled agonist, whereas antagonists have much higher affinity for sites labelled with radiolabelled antagonists.

The data presented here apparently indicate a somewhat different situation for the adenylate cyclase-coupled β-adrenergic receptors of frog erythrocytes. Binding displacement curves using the radioligand agonist and antagonist seem to be in close agreement. A slight but systematic and statistically significant difference does exist for weak agonists which are somewhat (two-to eightfold) more potent in displacing the labelled agonist than the antagonist. The significance of this finding is not clear at present.

These findings do not exclude the possibility that there may be separate 'agonist' and 'antagonist' conformations of the β-adrenergic receptors in frog erythrocyte membranes. If such do exist, however, our data indicate that they are freely interconvertible in the membranes and in the assay conditions used in these experiments. These observations are in marked contrast to several other receptor systems noted above, wherein agonist and antagonist binding give strikingly different results[7–11].

The ability to study the adenylate cyclase-coupled β-adrenergic receptors with both agonist and antagonist radioligands should provide new insights into the nature and regulation of these receptors.

Development of β-adrenergic receptor subsensitivity by antidepressants

CONSIDERABLE evidence exists that the tricyclic antidepressant drugs are selective inhibitors of monoamine uptake into monoaminergic nerve terminals[1,2]. These drugs also potentiate pharmacological responses to the monoamines in both the peripheral and central nervous systems[3–6]. These effects do not explain the discrepancy between the time-course of the biochemical and pharmacological responses which are elicited by these antidepressant drugs within minutes or hours and their clinical antidepressant action which requires treatment for weeks for efficacy to be reached. Furthermore, desipramine, an antidepressant drug, can potentiate neuronal responses to noradrenaline and dopamine in the caudate nucleus[7], although it does not block the catecholamine uptake in this area of the brain[1,2]. Finally the antidepressant iprindole does not influence noradrenaline turnover[8] or metabolism[9,10] or its uptake into catecholaminergic neurones[11], but is effective in potentiating the responses of single cortical and caudate neurones to monoamines[12]. Vetulani and his associates[13] suggested that the therapeutic action of tricyclic antidepressants may be related to postsynaptic adaptive changes in the sensitivity of the noradrenergic adenylate cyclase receptor system rather than to acute presynaptic events. The purpose of the experiments described here was to explore the molecular basis for antidepressant-induced noradrenergic subsensitivity by examining the kinetic properties of the β-adrenergic receptors in the microsomal suspension of rat brain by using a potent β-adrenergic receptor antagonist ^{3}H-dihydroalprenolol as a radiolabelled ligand[14–19]. Our results indicate that the main mechanism is a reduction in the number of receptors.

Specific ^{3}H-dihydroalprenolol binding to the microsomal fraction obtained from brain in control and in desipramine, iprindole- and doxepin-treated rats is shown in Table 1. When the concentration of ^{3}H-dihydroalprenolol was 4 nM, the specific binding to the control preparation was found to be 70 pmol per g protein. Chronic treatment of rats with desipramine, iprindole and doxepin decreased the specific binding by 65.5%, 42.3% and 30.6% as compared to control, respectively. This observation suggests that the resistance of adenylate cyclase to noradrenaline following chronic administration of antidepressants is due to subsensitivity of noradrenergic β-receptors. This decreased sensitivity of β-adrenergic receptors towards actecholamines following chronic administration of antidepressants may be due to alterations of the apparent affinity of these receptors to dihydroalprenolol or to a decrease in the number of β-adrenergic receptor sites. The dissociation constants of ^{3}H-dihydroalprenolol and the densities of the β-adrenergic receptors in control and desipramine-treated rat brain membrane fractions were determined by measuring the specific binding of various concentrations of ^{3}H-dihydroalprenolol and analysing the data by the method of Scatchard[20]. Only a single class of high affinity binding sites (Fig. 1) for ^{3}H-dihydroalprenolol could be detected in rat brain microsomes.

Table 1 Effect of chronic administration of antidepressants on specific dihydroalprenolol binding

Drug treatment	Specific ^{3}H-dihydroalprenolol binding pmol per g protein
None	70.0±3.5
Desipramine	24.2±1.5 ($P < 0.001$)
Iprindole	40.4±2.8 ($P < 0.001$)
Doxepin	48.6±2.4 ($P < 0.001$)

Desipramine, iprindole and doxepin were injected intraperitoneally in male, Sprague–Dawley rats, weighing 180–220 g, at a dose of 10 mg per kg body weight daily for 6 weeks. The rats were killed 1 h after the last injection by decapitation and the brains were rapidly removed and chilled in ice-cold 0.9% NaCl. The whole brain minus cerebellum was homogenised using a Brinkman Polytron, in 20 volumes of ice-cold 0.05 M Tris buffer (pH 8.0 at 25°), and centrifuged at 49,000*g* for 15 min. The pellet was rehomogenised in the same buffer and centrifuged as before. The pellet was finally resuspended in 50 volumes of Tris buffer (pH 8.0 at 25°) and used fresh for the binding assay. ^{3}H-dihydroalprenolol (32 Ci mmol^{-1}) binding was determined at 23 °C by combining 0.97 ml of the above particulate suspension, 4.0 nM ^{3}H-dihydroalprenolol and sufficient distilled water to make 1 ml as the final volume of the reaction mixture. After 20 m in incubation, the reaction mixtures were filtered under reduced pressure through Whatman glass fibres (GF/B). The filters were rinsed four times with 4 ml ice-cold Tris buffer to remove most of the unbound radioactive ligand. The filter papers were dried and placed in a counting vial containing 10 ml of Scintiverse (Fisher) and counted in a Packard Tri-carb liquid scintillation spectrometer (Model 3380) at 30% efficiency. Corrections were made for nonspecific accumulation of radioactivity by assaying parallel incubations which contained a large excess (100 μM) of noradrenaline. Specific binding, defined as the difference between total and nonspecific radioactivity was 60–70% of the total binding. Values are means ± s.e.m.

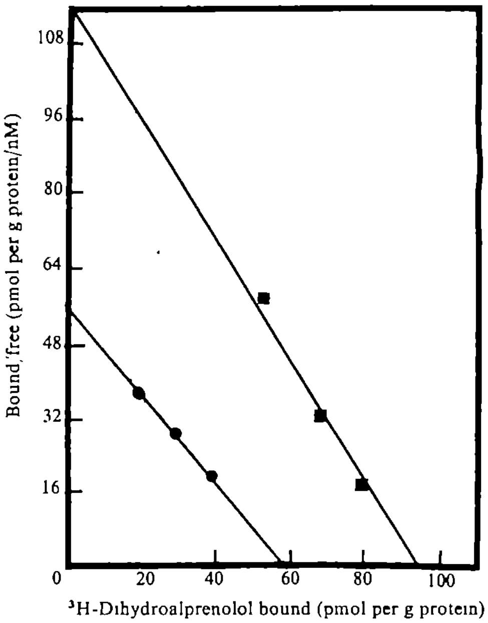

Fig. 1 Scatchard analysis of specific ^{3}H-dihydroalprenolol binding in brain microsomal fractions of control (■) and desipramine (●) -treated rats. The concentrations of ^{3}H-dihydroalprenolol used varied from 0.5 to 4.0 nM. (Procedure as for Table 1.) Dissociation constant and maximal number of binding sites were calculated from this figure and given in Table 2.

This observation is in agreement with the previously reported results of Bylund and Snyder[19]. The dissociation of ^{3}H-dihydroalprenolol binding to control rat brain particulate fraction was found to be 0.82 nM and this value is similar to the affinity constant (1.3 nM) of β-adrenergic receptors to ^{3}H-dihydroalprenolol reported by Bylund and Snyder[19]. Although the dissociation constant of ^{3}H-dihydroalprenolol to β-adrenergic receptors did not increase significantly, the density of receptors markedly decreased following chronic administration of desipramine (Table 2). This would suggest that chronic administration of desipramine leads to a decrease in the density of β-adrenergic receptors.

There are several lines of evidence indicating that modification of the presynaptic activity of noradrenaline, by altering, its rate of synthesis, release, uptake or storage, causes changes at the postsynaptic sites which are manifested as supersensitivity or subsensitivity. Such alterations in the sensitivity of the postsynaptic receptors for noradrenaline have been demonstrated by measuring noradrenaline-stimulated accumu-

Table 2 Scatchard analysis of specific ^{3}H-dihydroalprenolol binding to brains of control and chronically desipramine-treated rats

Brain preparation	Dissociation constant (nM)	Density of receptors (pmol per g protein)
Control	0.82 ± 0.08	95 ± 5
Desipramine treated	1.09 ± 0.14	59 ± 3
	$(P > 0.05)$	$(P < 0.001)$

The dissociation constants of ^{3}H-dihydroalprenolol and the density of binding sites were determined by Scatchard analysis[20]. The procedures for the preparation of the particulate fraction and measurement of specific binding of ^{3}H-dihydroalprenolol to membrane fractions are described in Table 1. Each experimental point is the average of nine determinations obtained from three animals in each group.

lation of cyclic AMP after administration of drugs such as 6-hydroxydopamine, cocaine and reserpine[21-23]. In general, drugs that decrease the activity of noradrenaline at the presynaptic sites cause supersensitivity as opposed to drugs that produce subsensitivity by increasing noradrenaline levels at the synaptic cleft. Vetulani and his associates[13] have provided evidence that chronic administration of antidepressants leads to subsensitivity of noradrenaline stimulated adenylate cyclase. Our results suggest that this resistant state of adenylate cyclase towards noradrenaline after chronic administration of antidepressants is due to a decrease in the number of β-adrenergic receptors. A hypothesis that β-adrenergic catecholamines are able to regulate catecholamine sensitivity of tissues *in vivo* by regulating the number of β-adrenergic receptors has been advanced[24]. The effect of desipramine provides some support to the above hypothesis. On the other hand, iprindole, with a minimal effect at presynaptic neurones, caused β-adrenergic receptor subsensitivity (Table 1).

The results suggests that although the level of noradrenaline may have an important role in controlling β-adrenergic receptor density, the concentration of this neurotransmitter at the synaptic cleft is not the only mechanism for the regulation of β-adrenergic receptor concentration.

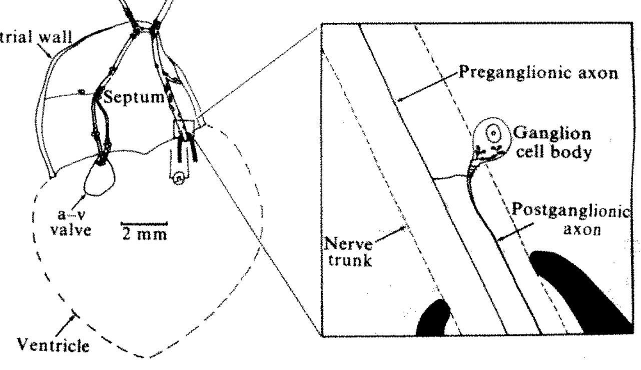
Formation of synapses between parasympathetic neurones deprived of preganglionic innervation

MUSCLE fibres will accept innervation from a foreign nerve only if synaptic transmission from the appropriate nerve has been interrupted[1]. The native nerve supply thus exerts an influence which renders muscle resistant to abnormal innervation. Do such influences act to prevent neurones from receiving inappropriate synapses? In the central nervous system (CNS) surviving inputs to partially denervated neurones will sprout to form additional synapses on those same neurones[2-4]. Furthermore, in partially denervated autonomic ganglia, surviving inputs will sprout to form synapses on postganglionic neurones they did not innervate originally[5-7]. But there has been no electrophysiological demonstration that denervated neurones will spontaneously receive synapses from a class of nerve cells with which there is normally no contact. We report here that the parasympathetic ganglion cells of the frog heart form functional synaptic connections with each other when their preganglionic synaptic input is removed; these intraganglionic connections do not occur normally.

The parasympathetic ganglion cells of the frog heart lie along two major nerve trunks in the interatrial septum (Fig. 1*a*)[8]. These trunks, which are extensions of vagal nerve branches, enter the heart at the sinus venosus, traverse the septum and pass into the ventricle. Stimulation of the nerve trunks at the point where they pass into the ventricle (Fig. 1*b*) results in antidromic activation of most ganglion cells in the septum (see Fig. 2*a*).

We searched for synaptic connections between ganglion cells by stimulating the nerve trunks antidromically and recording intracellularly from individual cells. In normal ganglia this procedure is complicated by the fact that synaptic potentials may result also from antidromic stimulation of preganglionic axons, branches of which sometimes extend as far as the ventricular edge of the septum (Fig. 1*b*)[9]. This complication was avoided by carrying out all experiments 2 d or more after vagotomy, by which time preganglionic transmission has ceased. The hearts of *Rana pipiens* were denervated by bilateral resection of the vagus nerve[10], and reinnervation was delayed

Fig. 1 Schematic view of the frog interatrial septum. *a*, Ganglion cell bodies (not drawn to scale) are seen along the two nerve trunks that pass through the septum. One of the a–v valves has been removed, and the nerve trunk has been drawn into a suction electrode (stippled) for antidromic stimulation of ganglion cells (see expanded view in *b*).



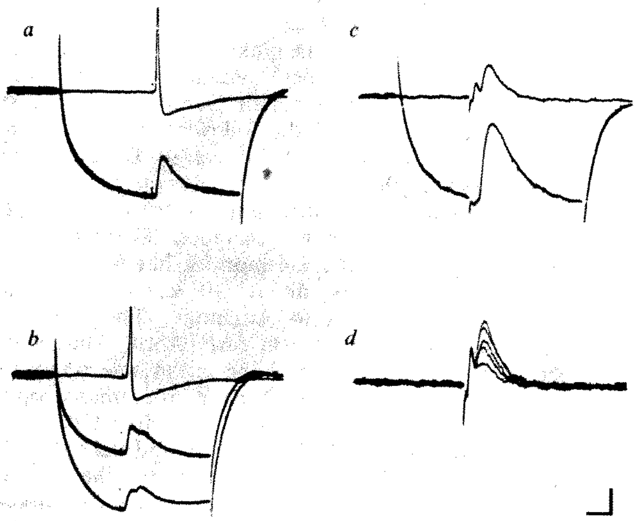


Fig. 2 Action potentials and synaptic potentials recorded intracellularly from frog cardiac cells. *a*, An antidromic action potential was elicited by nerve trunk stimulation (upper trace). When the cell was hyperpolarised by current injected through the recording electrode, the action potential failed to invade the cell body and appeared instead as a monotonic depolarisation (lower trace). This neurone was denervated 4 d previously to allow degeneration of the preganglionic fibres. *b* And *c*, both action potentials and synaptic potentials were elicited from ganglion cells deprived of preganglionic input for 2–3 months. *b*, Neurone responding to antidromic stimulation with an action potential, apparently without a synaptic potential (upper trace). When the cell was hyperpolarised by current passed through the recording electrode, however, a small synaptic potential was seen on the falling phase of the blocked action potential (middle trace). Further hyperpolarisation reduced the amplitude of the blocked action potential and enhanced the synaptic potential (bottom trace). *c*, Antidromic stimulation elicited an action potential that did not invade the cell body and a synaptic potential. The action potential was not observed on hyperpolarisation and the synaptic potential was enhanced. *d*, The amplitude of this same synaptic potential fluctuated in response to repeated stimuli of constant intensity in a manner characteristic of low quantal content synaptic transmission (five stimuli, delivered at 0.3 Hz). Horizontal calibration 20 ms; vertical calibration, 20 mV in *a* and *b*, 10 mV in *c*, 5 mV in *d*. Experiments were carried out in Leibovitz-15 medium diluted to 40% and supplemented with inorganic salts, glucose and buffer to give the following concentrations (in mM): NaCl, 114; KCl, 2.1; $CaCl_2$, 3.6; $MgCl_2$, 0.8; glucose, 5; HEPES, 5; *p*H, 7.2. Electrophysiological recordings were made with micropipettes filled with 4 M potassium acetate and bevelled to resistances of 60–120 MΩ. Only cells which had resting potentials more negative than −40 mV were studied.

by a second resection 50–60 d after the first. In experiments carried out long after denervation, the possibility of vagal reinnervation was checked by orthodromic stimulation of the vagus nerves; septa which had been reinnervated were not used.

Synaptic potentials elicited by antidromic nerve stimulation were not detected in septa denervated for short times. In nine animals examined 2–5 d after denervation, no synaptic potentials were encountered in 200 neurones examined (175 responded with antidromic action potentials). We conclude that intrinsic synaptic connections are absent in normally innervated septa. In contrast, however, in seven septa denervated for 60–100 d, antidromic stimulation elicited synaptic potentials from 52 of 107 neurones examined (93 responded with antidromic action potentials). No significant difference in resting potentials or input resistance was noted between these cells and those denervated for short times. Sample recordings from two neurones that show both antidromic action potentials and synaptic potentials are reproduced in Fig. 2*b* and *c*. The synaptic origin of these potentials is indicated by the fact that they were enhanced by hyperpolarisation, that they were abolished by 10^{-4} M *d*-tubocurarine, and that their amplitudes often showed fluctuations characteristic of low quantal content transmission (Fig. 2*d*).

Two kinds of experiments were carried out to show that the synaptic potentials recorded in denervated ganglia arise from connections between the ganglion cells. In the first, to demonstrate synaptic coupling between pairs of ganglion cells, an intracellular recording was made from one neurone while the cell bodies of neighbouring neurones were stimulated extracellularly (see Fig. 3*a*). The probability of success of this experiment was low since usually less than 2% of the cells in the septum were accessible for stimulation within a single field of view (diameter 400 μm). In 2 of 388 pairs tested, extracellular stimulation of one ganglion cell produced a synaptic potential in another (Fig. 3*b*). In the second group of experiments, we searched for synaptic potentials in septa which had been denervated chronically and then isolated and maintained *in vitro*. Since parasympathetic ganglion cells are the only neurones whose cell bodies lie within the septum, only these cells should remain viable in isolated septa. Indeed, when normal heart septa were cultured at 22 °C, preganglionic synaptic transmission failed in 24–36 h. In contrast, synaptic potentials could be elicited by antidromic nerve trunk stimulation from many neurones in septa denervated for 3 months and then maintained *in vitro* for 3–4 d (14 examples in 46 cells examined; culture medium as described in Fig. 2 legend, supplemented with foetal calf serum and antibiotics). We conclude that the synaptic potentials elicited in isolated septa result from synaptic interaction between ganglion cells.

Our results indicate that prolonged loss of normal preganglionic input leads to the formation of excitatory synapses

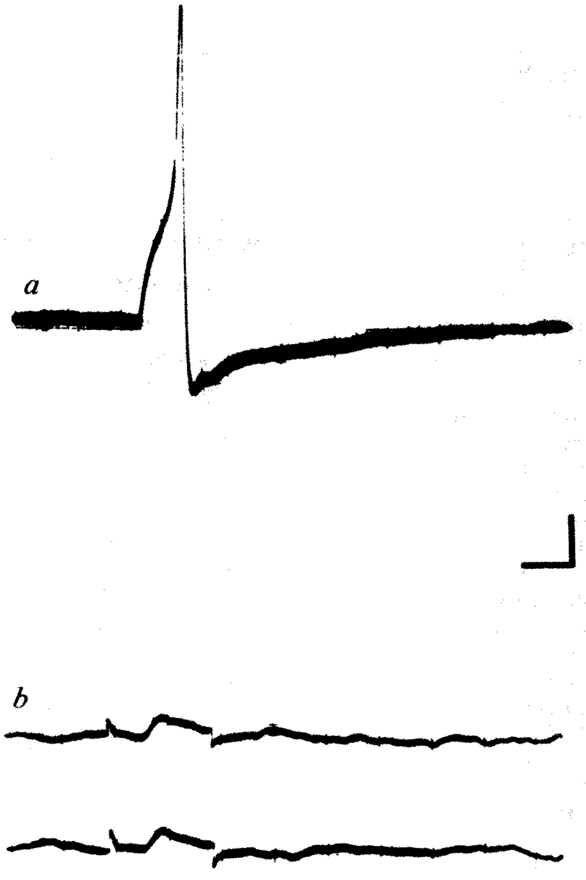

Fig. 3 Direct demonstration of synaptic interaction between ganglion cells. *a*, Stimulation by a blunt extracellular micropipette elicited an action potential from a ganglion cell. *b* (a different experiment), three successive e.p.s.ps recorded from a neurone in response to extracellular stimulation of another nerve cell 300 μm distant (40-ms stimulation pulses). Calibration: 10 mV, 20 ms.

between frog parasympathetic neurones. These postganglionic collateral synapses do not exist normally in frog, whereas they do in the mudpuppy cardiac ganglion[11,12] and in the superior cervical ganglion of guinea pig[7]. These connections also develop between dissociated rat sympathetic ganglion cells in culture[13,14]. The capacity to form collateral synapses in frog presumably arises in part because acetylcholine is both the pre- and the postganglionic transmitter in the cardiac ganglion. Experiments are now in progress to determine the fate of these intraganglionic synapses following reinnervation of ganglion cells by their normal vagal inputs.

Synaptic and septate neuromuscular junctions in embryonic lobster muscle

IT is generally accepted that there is not enough genetic material to programme uniquely the structure of each neurone in multicellular animals. This then presents the problem of determining how a growing neurone finds and identifies the correct postsynaptic structures. Work on the visual system of *Daphnia* has demonstrated that the primary sensory neurones form transient gap junctions with undifferentiated neuroblasts in the optic lamina[1]. No similar work has been reported for interneurones or motor neurones, however. For instance, we do not know how developing motor neurones find the proper muscle in the periphery[2]. I studied neuromuscular development in lobster embryos and report here that motor neurones form septate junctions with developing muscle cells in the abdomen. In addition, mature neuromuscular synapses are present in the embryo as early as the third to fourth month of the total 9 month development.

Crustacean neuromuscular systems offer several advantages for studying developmental processes. Each muscle is innervated by a few identifiable neurones, at least one of which is inhibitory. Muscle fibres each receive multiple inputs, but not all fibres within a muscle are identically innervated[3,4]. For these reasons, it has been suggested that these systems might serve as useful models to study processes which occur in central nervous systems[5]. Previous work on developing arthropod neuromuscular systems has been limited primarily to studies on insect larvae[6,7]. One ultrastructural study on developing crayfish opener muscle suggested that active synapses were not present just before hatching[8].

Egg-bearing lobsters (*Homarus americanus* Milne-Edwards) were trapped in local waters around Woods Hole, Massachusetts, and kept in tanks of running seawater at ambient temperatures. These animals extrude and fertilise the eggs during September or October, then brood them under the abdomen until the following May or June, when the larvae all hatch within 1–2 d (ref. 9). Development is not constant during this period; after extrusion, development proceeds for several months until water temperature falls below about 10 °C during December. There is little development for the following 5–6 months, but when water temperature again reaches about 10 °C, during late April, development proceeds to hatching[10]. The embryos used in this study were removed in early April. Abdomens were isolated from the thorax and the telson was removed to permit penetration of fixative for electron microscopy. Fixation was in 2% glutaraldehyde, 1% formaldehyde, 100 mM cacodylate at *p*H 7.4, 4% sucrose and 0.5% NaCl. Manganese chloride (0.1%) was added to the initial fixative to prevent release of synaptic vesicles during fixation (unpublished). Sections were cut on a diamond knife and post-stained with uranyl acetate and lead citrate.

The abdominal muscles do not differentiate synchronously during development. In all embryos fixed between December and April it was possible to observe fully differentiated short (1.5–2.5 μm) and long (2.5–4.0 μm) sarcomere muscle fibres as well as undifferentiated muscle cells. Synaptic profiles, which were generally similar to those seen in adult muscle, were observed only on mature muscle fibres (Fig. 1). Growing axons were characterised by the presence of two populations of vesicles, one with a diameter of about 40–50 nm and the other a diameter of about 60–90 nm (Figs 2 and 3). The former are the same size as the vesicles normally observed in lobster excitatory synapses. But, in the growing axons many of the vesicles were electron opaque while those in neuromuscular synapses are agranular. The second, larger type of vesicle is similar to the dense-cored vesicles of unknown function which have been described in a wide variety of neuromuscular synapses[11].

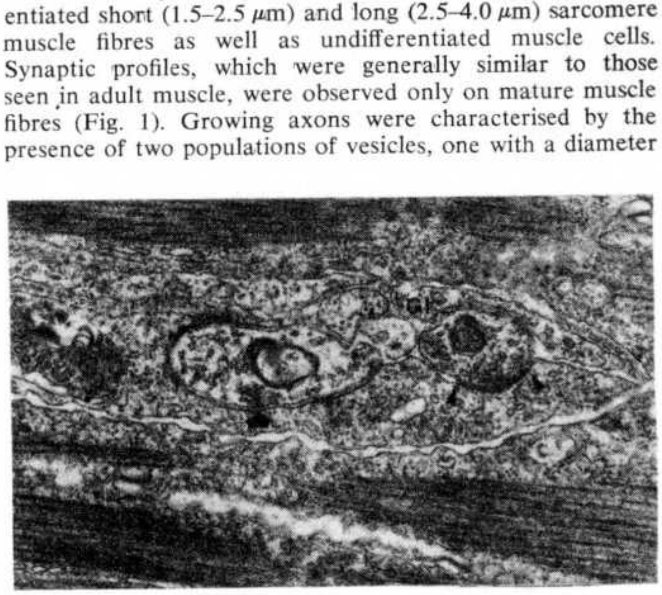

Fig. 1 Excitatory and inhibitory neuromuscular junctions on embryonic lobster muscle. The excitatory terminal (right) has the characteristic round synaptic vesicles. The synaptic region has a heavily stained pre- and postsynaptic membrane (between arrowheads). Densely staining material is present in the synaptic cleft. The inhibitory terminal (left) contains smaller, irregular vesicles and the pre- and postsynaptic membranes are characteristically not heavily stained (see ref. 8). A presynaptic dense body, with vesicles clustered around it, is present (arrow). These nerve terminals are on a long sarcomere fibre; similar terminals are observed on short sarcomere fibres. (×28,200.)

The growing ends of the axons are always observed in proximity to embryonic muscle cells and are characterised by several features. First, vesicles are invariably present in rather high densities. Second, growth cones or 'microspikes'[14] are present and are packed with vesicles (Figs 2, 3). Third, a number of tubular structures are

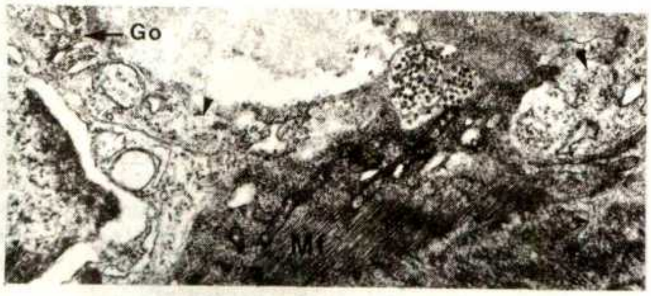

Fig. 2 Growth cone of a motoneurone in abdominal muscle of embryonic lobster. The growth cone is characterised by the presence of numerous vesicles ranging from about 50–90 nm in diameter (see text). The cone, which is adjacent to an embryonic myotubule, appears to be in the process of dividing. Note microtubules (arrowheads), Golgi apparatus (Go) and myofilaments (Mf) in the myotube. (×9,000.)

present. Some of these seem to be neurotubules but others enlarge into vesicular structures and may represent some type of endoplasmic reticulum. These axons, unlike mature motor axons, are never covered with glial cells.

The muscle cells that are associated with the growing axons have a distinctive appearance different from mature muscle fibres. They resemble the myotubes described for developing vertebrate muscle[12]. There are never any sarcomeres present but near the border there is always a band of myosin with interdigitating actin filaments (Figs 2, 3). This band is often adjacent to an area of very dense sarcoplasm. The borders of the muscle cell always contain microtubules and a granular substance, probably glycogen. Microtubules are present in mature muscle fibres, but never in the density observed in these embryonic muscle cells, except at the tendonal ends (unpublished, and see ref. 13).

A small process of a growing neurone has been observed to form a septate junction[15] with a muscle cell, possibly a myoblast (Fig. 4). The neurone is characterised by the presence of numerous vesicles. The other structure has features characteristic of embryonic muscle cells; the granular sarcoplasm contains mitochondria and microtubules. It is unlikely to be a glial cell as these have not been observed around the growing ends of the motor axons. In any case, septate junctions are not common features in the embryonic neuromuscular system. In the thirty preparations examined, extensive portions of growing axons were observed in five specimens, lesser portions in two other specimens. Only two septate junctions have been observed, however; thus these connections may be rare, transient[1] or both.

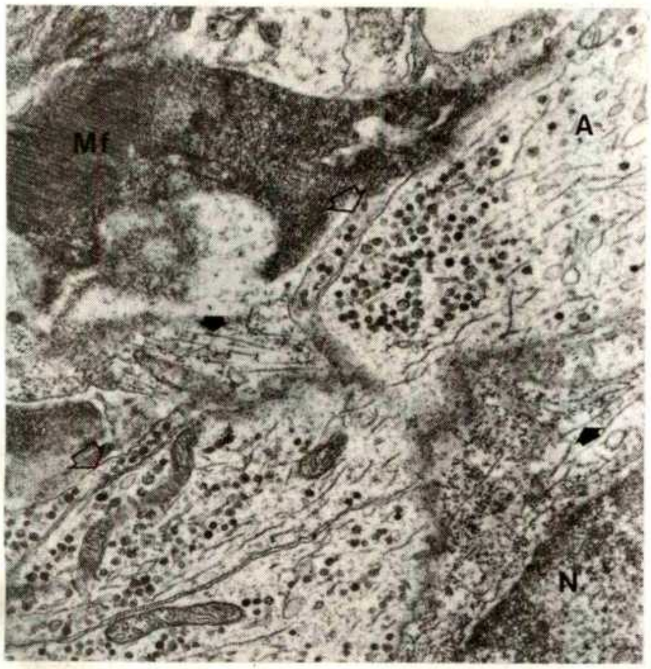

Fig. 3 Growing region of axons (A) which is overlying an embryonic muscle cell. Two 'microspikes', filled with vesicles, are present (open arrows). The muscle cell nucleus (N) is at the bottom right. The sarcoplasm contains microtubules (filled arrows) and glycogen. A band of myofibrils (Mf) is present in the upper left. (×16,625.)

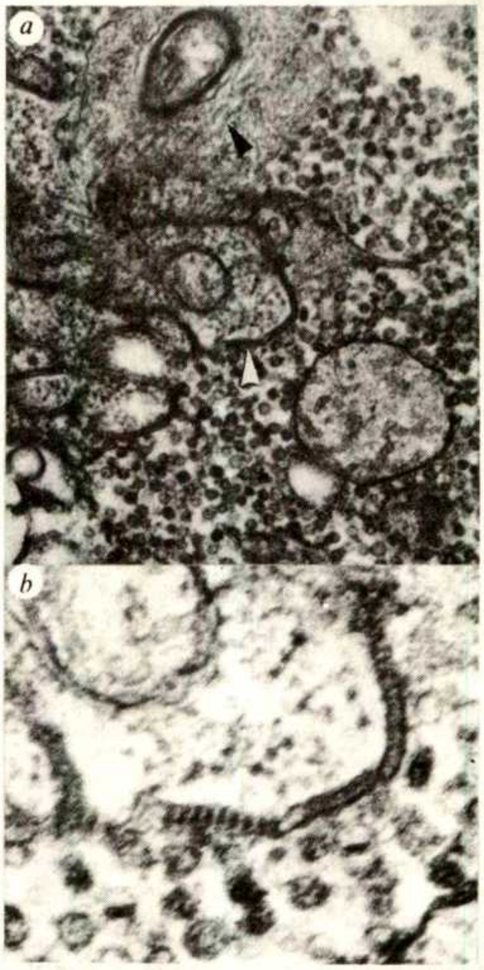

Fig. 4 Septate junction between a growing motoneurone and an embryonic muscle cell, probably a myoblast. The muscle cell has the characteristic granular sarcoplasm and microtubules (dark arrowhead). The neurone is filled with vesicles and has several small projections. *b*, An enlargement of the septate junction (white arrowhead) shown in the middle of *a* figure. (*a*, ×31,540; *b*, ×92,960.)

These results demonstrate that lobster motor axons can have two types of connections with muscle during embryogenesis. The growth cones of growing axons form septate junctions with immature muscle cells. This might well be a period when the two different cell types can exchange chemical information. Later, when the muscle fibres have differentiated to a stage where sarcomere formation is well advanced, mature synaptic endings can be observed. Intracellular recording from these muscles has revealed that the synapses are indeed active. As early as the third month of development miniature excitatory postsynaptic potentials (e.p.s.ps) can be observed. Occasional spontaneous e.p.s.ps and inhibitory postsynaptic potentials have also been observed (in preparation). Thus it seems that both growth cones and active synapses may be present on these motor axons at the same time.

Is recombination confined to structural genes on the eukaryotic genome?

THE size of the eukaryotic genome increases with the evolutionary complexity of the organism, although this relation is somewhat obscured by large differences in the haploid DNA content of closely related species. Yet the total number of genes is believed to be fairly constant, suggesting that genes of higher eukaryotes correspond to much larger DNA segments than in microorganisms[1]. In that case, only a small fraction of each gene would code for the ultimate gene product, the remainder being 'spacer' DNA with still ill-defined functions. The sequence coding for the gene product will be hereafter designated as the structural gene. The complex organisation of chromatine in higher organisms raises the problem of its possible influence on the distribution of recombination events. I shall present here evidence suggesting that they may well be restricted to small regions of the genome, possibly corresponding to the structural genes.

The basic argument is that the length of total chromosome maps is fairly constant among eucaryotes (Table 1, Fig. 1) and that the same applies to intragenic fine-structure maps among the few organisms where they have been extensively investigated (Fig. 1*b*) such as several fungi, *D. melanogaster*, rice and maize. The conservation of the total recombinational length of eucaryotic genomes means that the average frequency of crossover per unit length of DNA decreases by several orders of magnitude from lower to higher eukaryotes (Table 1, column 4). As opposed to intergenic crossover, intragenic recombination is mainly a non-reciprocal exchange. Yet, both seem to be related processes resulting from the formation of hybrid DNA molecules[2,3]. There are theoretical grounds to believe that they are either in the same, or in a 1/2 ratio with respect to actual distances[4]. If one further assumes that exchanges are randomly distributed on the genome and that intragenic maps correspond to the structural gene even in higher eukaryotes, the length of intragenic maps should considerably decrease from lower to higher eucaryotes.

The comparison of intragenic maps is complicated by two factors. First, recombination within a gene is not always proportional to actual distances, because of marker effects which are more or less prevalent depending on the organism investigated. Second, different regions of the genome have a different density of exchange per unit length of DNA, resulting in marked heterogeneities in the length of intragenic maps within one organism (Fig. 1*b*). On the whole, however, the length of intragenic maps are roughly comparable in all eukaryotes investigated (Table 1, column 2 and Fig. 1*b*).

A key issue here is whether intragenic maps correspond to DNA stretches of comparable length in all eukaryotes. If intragenic maps were to include not only the structural genes but also the surrounding spacers, they would correspond to comparatively long DNA fragments in higher eukaryotes. This would compensate for the general decrease in the average frequency of recombination per unit length of DNA, and may result in the recombinational length of genes being fairly constant for all organisms. However, evidence suggests that point mutations in the spacers do not, as a rule, prevent gene expression (in other words, that intragenic maps are limited to the structural genes).

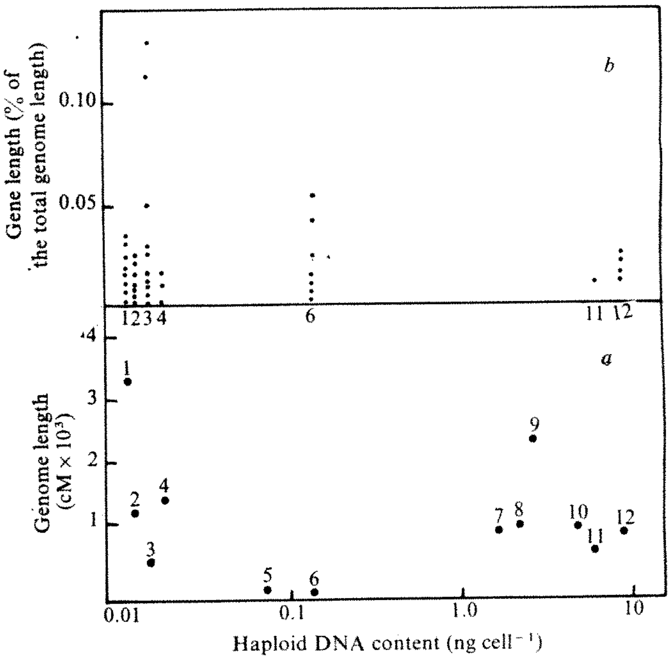

Fig. 1 Recombination frequencies as a function of haploid DNA content. (*a*) Total genome length in centimorgans (cM). (*b*) Length of individual intragenic maps as a fraction (per cent) of the total genome length. Each point represents an individual gene map as given in Table 1, column 2. Haploid DNA content from refs 9, 10 and 11, except for *N. crassa*[39], *A. nidulans*[30], *C. radiatus*[31], *C. elegans*[23], *O. sativa*[32] and *P. sativum*[40]. The organisms represented are: *S. cerevisiae*[1], *S. pombe*[2], *N. crassa*[3], *A. nidulans*[4], *C. elegans*[5], *D. melanogaster*[6], *L. esculentum*[7], *M. musculus*[8], *H. sapiens*[9], *P. sativum*[10], *O. sativa*[11], and *Z. mays*[12].

First, it is established that spacers of rRNA evolve much more rapidly than the structural loci themselves[5] indicating, in that case at least, that there is no stringent requirement imposed on the spacer sequence. Second, work on the *rosy* locus of *D. melanogaster*[8] has shown full coincidence between an intragenic map constructed on 'null' mutants and another based on mutants with altered electrophoretic properties in the gene product, that is, mutants defining the structural locus. Similar evidence is available at two other loci of *D. melanogaster*[7,8]. Finally, the frequency of spontaneous forward mutation per locus per gamete is similar for yeasts, *D. melanogaster*, and mouse (Table 2) which suggests again that genes (defined as loci mutable to non-complementing alleles with a null phenotype) correspond to the same length of DNA in all eukaryotes.

On the other hand, the frequency of forward mutation per locus increases with the size of the genome when mutation is induced by X rays[9] or by ethyl methane sulphonate[10] (see ref. 11 for a critical evaluation of these data). X rays and perhaps EMS-induced intralocus mutants, however, are often deletions or equivalent multisite events in higher eukaryotes, whereas they are exclusively point mutations in fungi (see ref. 12). X rays do induce deletions in fungi, but these are multilocus events covering

*In most cases, roughly linear maps can be constructed on the basis of two-factors crosses, thus supporting the assumption that intragenic frequencies of recombination are proportional to the actual distances on the gene and providing a direct estimate of the recombinational length of the gene. When necessary, recombination frequencies have been corrected for map expansion[4]. In some cases, the intragenic order of the alleles is quite ambiguous, and the recombinational length of the gene was assumed to be given by the heteroallelic combination giving the highest frequency of recombinant, though this need not define the largest distance in terms of base pair number. Total genome maps from ref. 20 except for *S. pombe*[34], *N. crassa*[18], *M. musculus*[33] and *H. sapiens*[35]. Except when not explicitly given, references for intragenic fungal maps are to be found in refs 2, 18 and 19, whereas data for *S. pombe* are either quoted in ref. 20 or come from unpublished work of Leupold and co-workers.

at least two genes and recoverable as recessive lethals in *N. crassa* dicaryons[13]. Thus, the differences in mutation rate could be due to deletions being retained as intralocus events as long as they remain within the boundaries of a single band in higher eukaryotes, whereas they are selected against in microorganisms where intercistronic regions are quite short.

Hence, it can be assumed that even in higher organisms the actual length of intragenic maps is about 1000 base pairs, corresponding to the structural gene and perhaps a few regulatory sequences such as promotors. This gives a rough estimate of the frequency of intragenic exchanges per kb, which can be compared with the average frequency of intergenic exchange calculated over the whole genome (Table 1, column 4). In lower eukaryotes (Ascomycetes), the frequencies of intragenic and intergenic exchanges are of the same order of magnitude. This is what would be expected on the hybrid DNA model for recombination[2-3-4]. In higher eukaryotes, the density of intragenic exchanges is comparable with what is found in fungi, but much higher than the density of intergenic exchanges calculated over the whole genome. That is, intragenic maps are of similar length in all organisms, whereas the frequency of crossover per unit length of DNA considerably decreases from lower to higher eukaryotes (Table 1, column 4). This is very striking for higher plants (*O. sativa*, *Z. mays*) where intralocus maps are about 500 times larger than expected from the extrapolation of crossover frequencies. The same probably applies to *D. melanogaster* although the data are more dispersed and, therefore, more difficult to interpret: Five loci are 10–50 times longer than expected from the extrapolation of crossover data, assuming an average gene to be 2 kb long (see also *albino* in spider mite). One locus (*ma–1*) is very short and would fit with a homogeneous distribution of intragenic versus intergenic exchanges. Two loci, (*garnet* and *rosy*, keeping in mind that *rosy* maps near the centromere in a region of unfrequent crossover) have intermediate values. On the whole, however, the data available for higher eukaryotes suggest a substantially greater frequency of recombination within, than between, the structural loci. If this is so, estimates of gene numbers in short regions of the genome such as the histo-incompatibility cluster of mammals should be revised, since the length of these regions (0.4 cM in mouse, see ref. 37) would be compatible with only a few genes.

Table 2 Frequency of spontaneous forward mutations per locus per gamete among eucaryotes (recalculated from papers quoted in ref. 12)

Organism	Screening system	Frequency of mutation/locus /gamete
S. pombe	Mutation to auxotrophy at five *ade* genes	1.6×10^{-6}
S. cerevisiae	Mutation to auxotrophy assuming 100 genes to lead to auxotrophic requirements	3.5×10^{-6}
D. melanogaster	Recessive lethals on chromosome I, II and III assuming 4,500 genes on these chromosomes	2.0×10^{-6}
M. musculus	Mutations at five coat colour loci	1.8×10^{-6}

A heterogeneous distribution of intragenic versus intergenic exchanges would have to be reconciled with the idea that both types of exchanges result from the formation of a hybrid DNA molecule[2,3]. One possibility is that, though hybrid DNA may occur with a roughly equal probability everywhere on the genome, strand isomerisation leading to crossover[2,3] is prevented by some features of the chromatine in higher eukaryotes. This would depress crossover without affecting non-reciprocal events. One would then expect, however, intragenic recombination to be predominantly associated with a parental distribution of flanking markers, which is not observed in the few cases analysed so far in *Z. mays*[14,15] or *D. melanogaster*[16,26].

I propose that this distribution of exchanges directly reflects the heterogeneous distribution of hybrid DNA on the chromosomes. That is, hybrid DNA formation may be mainly confined to the structural genes on the chromosomes of higher eukaryotes, in which case the frequency of exchanges per unit length of DNA should be much higher when calculated over short, intragenic distances than over the whole genome.

Cytological data show that the bulk of each chromosomal pair lies outside the synaptonemal complex and so cannot participate in recombination. It is not known whether this is randomly generated at each meiosis during the building up of the synaptonemal complex, or whether some mechanism restricts pairing always to the same stretches of the DNA, which may, for example, be regions with a dense distribution of structural genes. Alternatively, the necessity to keep the structural genes accessible to transcription may impose some basic constraint on chromatin organisation, resulting in them being preferentially accessible to hybrid DNA formation.

The fitness *ad equilibrium* of a polymorphic population is at a maximum in the absence of recombination[17], which may account for the linkage maps being roughly constant despite the increase in genome length. As for intragenic recombination, it results in the formation of new alleles and, provided a reasonably high degree of gene polymorphism is assumed, may substantially affect the speed of gene evolution. Unlike mutation, however, its rate might be easily modulated in a site-specific way, assuming that the specific *rec* genes of *N. crassa*[41] are of general occurrence in eukaryotes. It may then have been selected as advantageous by organisms placed in a variable environment.

I thank Irene Abraham, Hannes Gautschi, Robin Holliday and Urs Leupold for helpful comments. This work was supported by the Swiss National Science Foundation.

n-Butyrate causes histone modification in HeLa and Friend erythroleukaemia cells

LEDER and Leder[1] have reported that low concentrations of *n*-butyrate cause Friend erythroleukaemia cells to begin globin synthesis. Apparently *n*-butyrate can reverse that part of viral transformation which prevents the expression of differentiation in these cells. Prasad and Sinha[2] have summarised the effects of *n*-butyrate on neuroblastoma, HeLa, and other cell types. They and others[3–10] have seen reversible inhibition of proliferation, decrease of DNA content, morphological modifications, and increases in the production of specific enzymes, such as adenylate cyclase, alkaline phosphatase, and a sialyltransferase. The present paper describes rapid, dramatic, and reversible increases in histone acetylation in the presence of *n*-butyrate.

Nuclei from *n*-butyrate treated HeLa and Friend erythroleukaemia cells contain greatly increased amounts of modified forms of histone H4 (Figs 1, 2). Total histones from nuclei of cells after 24 h of treatment show several strong, slower moving H4 bands when examined in acid urea gels[11] and in Triton DF16-acid urea gels[12]. Their electrophoretic positions correspond to the mono-, di-, tri-, and tetra-acetylated H4 histones which occur during normal histone biosynthesis[13]. For this reason and because of the experiments described below, we believe the modified H4 histones to be acetylated. In control cells only a small amount of mono-acetyl-H4 is present, whereas this is the dominant component in treated cells. In HeLa cells the extent of modification, although marked at 1 mM, increases at higher *n*-butyrate concentrations (Fig. 1*a*). H4 acetylation and H3 modification in HeLa cells are already noticeable after only 1 h in 5 mM *n*-butyrate (Fig. 2), the earliest effect reported. Friend cells also show the acetylated-H4 pattern after 24 h in 1 mM *n*-butyrate; it becomes more pronounced at 3 mM (Fig. 1*b*).

In both HeLa and Friend erythroleukaemia cells the histone H4 pattern reverts to normal when cells treated with *n*-butyrate for 24 h are shifted back to control medium for a further 24 h (Fig. 1*c*, *d*).

In both cell lines there is also a clear alteration of the histone H3 band with an increase of slower moving material. This is a broadening of the H3 band rather than the appearance of new distinct bands. There is a striking increase in the relative amounts of H1 (Fig. 2). These changes are also reversible within 24 h after removal of *n*-butyrate.

To investigate the nature of the histone modification, total acid extracted histones from HeLa cells treated for 24 h with 5 mM *n*-butyrate were completely digested with trypsin and Pronase[14]. After separation from the proteolytic enzymes by Sephadex G25 column gel filtration, the free amino acids were analysed on a Durram analyser Model D500. A peak corresponding to ε-*N*-acetyl-lysine was found just in front of glycine in the position of a standard prepared from acetylated bovine serum albumin[15]. This peak was absent in the sample prepared from control cells. No evidence for ε-*N*-*n*-butyryl-lysine was found between alanine and valine in the position of an ε-*N*-*n*-butyryl-lysine standard. The amount of ε-*N*-acetyl-lysine was 1.7 mol per mol H4. It is not yet known whether these acetyl groups are all on H4 or whether they are more generally distributed. Quantitative analysis of the scans of gels shown in Fig. 2 indicated that the sum of the H4 components in *n*-butyrate treated cells was equal to the sum of the H4 components in control cells and that no H4 had been lost. The proportion of acetylated H4 reaches approximately 80% of total H4 at 24 h in 3 mM (Fig. 1*a*) or 5 mM *n*-butyrate (Fig. 2). In addition, we believe that the modification is

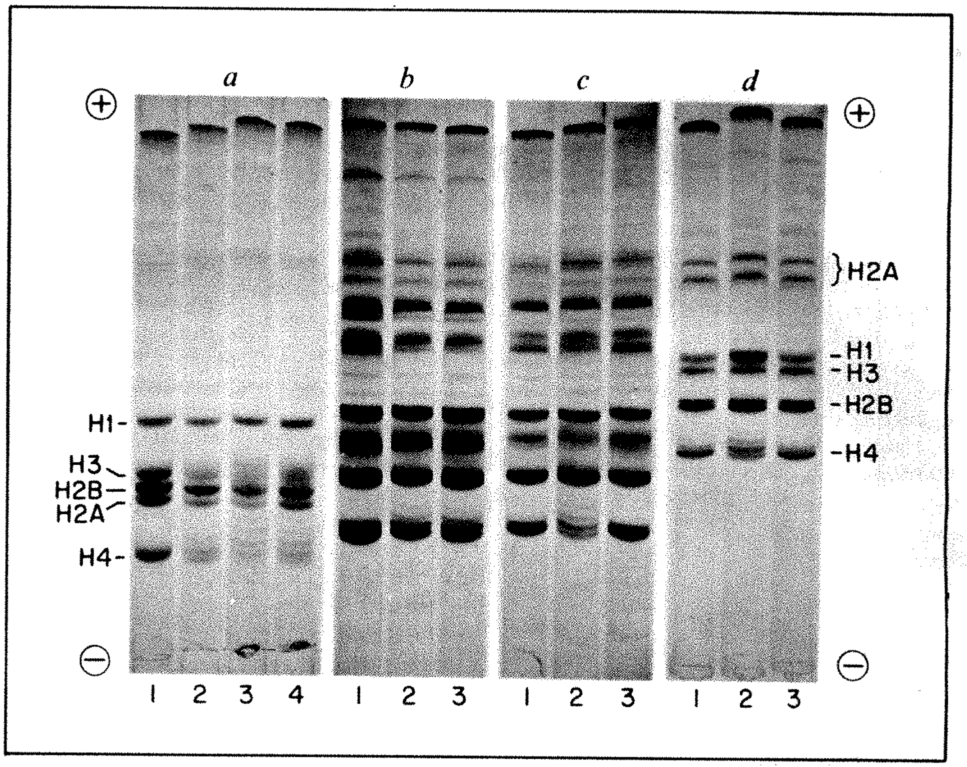

Fig. 1 Effect of *n*-butyrate on histone modification in HeLa and Friend cells. HeLa cells were maintained at 37 °C in suspension culture at 0.1–0.5 × 10^6 per ml in Joklik's modified minimum essential medium, containing 7% horse serum. Friend erythroleukaemia cells (clone 755-PC-4) (ref. 20) were grown at 37 °C in suspension in α medium[21] lacking nucleosides and supplemented with 15% foetal calf serum. They were maintained at 0.05–0.5 × 10^6 per ml to permit log-phase growth. Aliquots of a stock solution of 1 M Na *n*-butyrate in Ca^{2+}- and Mg^{2+}-free phosphate buffered saline (final *p*H 7.3) were added to cultures 24 h before histone extraction. Preparations of nuclei and histones were carried out at 0–4 °C. Nuclei were prepared from washed cells by Douncing and histones extracted[22] in 0.4 N H_2SO_4. *a*, Histones were precipitated with 10 volumes of acetone, dried and electrophoresed on acid–urea 15% acrylamide gels[11] at 20 °C for 5 h; the gels were prepared in 0.125% ammonium persulphate. *b*, *c* And *d*, histones prepared as before, were run on 15% gels containing 6 M urea and 0.38% Triton DF-16, according to the method of Alfageme *et al.*[12]. Staining was with 0.1% amido black in 40% methanol, 7% acetic acid. *a*, HeLa cells were either collected without *n*-butyrate treatment (gel 1) or after exposure to 1, 3, or 5 mM *n*-butyrate for 24 h (gels 2, 3, 4, respectively). *b*, Friend cells were collected without *n*-butyrate treatment (gel 1) or after exposure to 1 or 3 mM *n*-butyrate for 24 h (gels 2, 3, respectively). *c*, Untreated HeLa cells (gel 1), cells exposed to 5 mM *n*-butyrate for 24 h (gel 2), and 24-h *n*-butyrate-treated cells washed and resuspended in fresh medium without *n*-butyrate for 24 h (gel 3). *d*, Untreated Friend cells (gel 1), cells exposed to 1 mM *n*-butyrate for 24 h (gel 2) and 24-h *n*-butyrate-treated cells washed and resuspended in fresh medium without *n*-butyrate for 24 h (gel 3).

acetylation and not phosphorylation, since incubation of the modified histones with *Escherichia coli* alkaline phosphatase[16] leaves the modified H4 pattern intact.

We are particularly interested in the effect of *n*-butyrate on the proliferating malignant Friend erythroleukaemia cell and on the proliferating HeLa cell, which is also derived from a malignant cell. In the Friend cell differentiation is blocked. *n*-Butyrate induces the continuation of differentiation and the production of specific products, as well as the striking accumulation of acetylated histones. We do not know whether there is a causal relationship between histone acetylation and these observations. Darzynkiewicz *et al.*[17] and Nudel *et al.*[18] have reported subtle changes in the structure of Friend cell chromatin using either dimethyl sulphoxide (DMSO) or *n*-butyrate as inducing agents.

It is not known whether *n*-butyrate affects tumorigenicity of the Friend cell or whether it affects DNA synthesis. If it behaves like the original inducing agent, DMSO, we would predict a decrease in tumorigenicity and, by analogy with our HeLa cell experiments (Hagopian, M.G.R., Swartz and V.M.I., in preparation), an

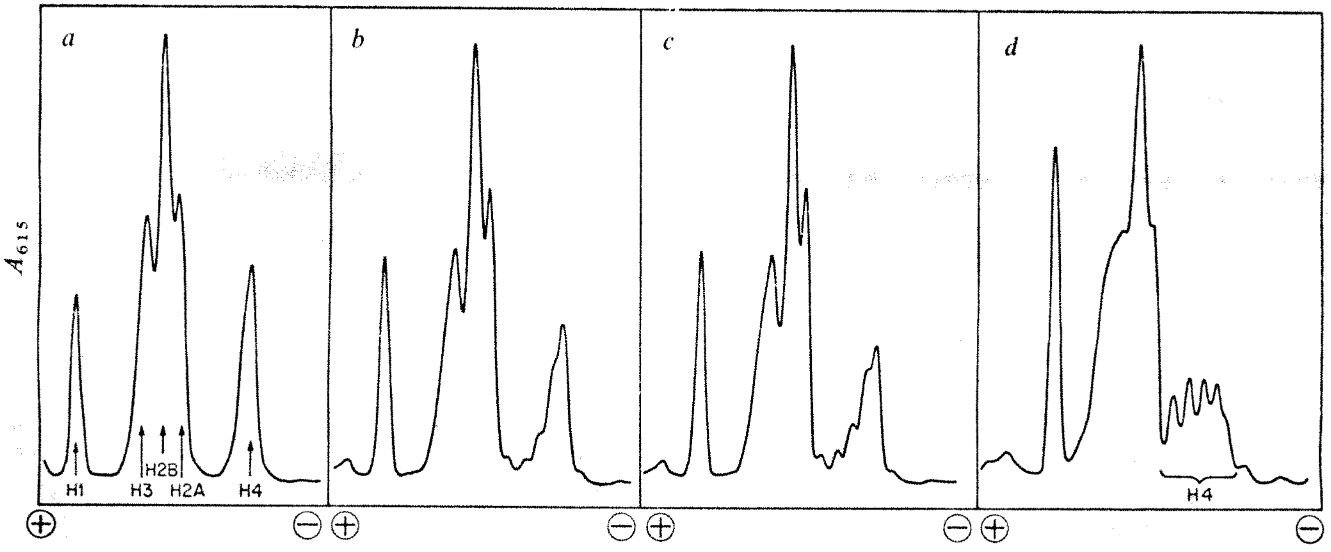

Fig. 2 Time course of *n*-butyrate effect on HeLa histones. Nuclei were prepared and histones extracted as described in Fig. 1. Cells had been exposed to 5 mM *n*-butyrate for *b*, 1 h; *c*, 2 h and *d*, 24 h. Samples were electrophoresed on acid urea gels and stained as in Fig. 1. The gels were scanned at 615 nm with the full scale absorbances adjusted to normalise peak H2B. *a*, Control.

inhibition of DNA synthesis. Moore and Chalkley[19] using cultured hepatoma cells suggest an interdependence of the level of histone H4 acetylation and the rate of cell division. We do not observe acetylation changes in the histone patterns of DMSO-treated Friend cells (J.R.N., unpublished); perhaps the two agents act at different points of these complex processes. Further experimental work is needed to look for a causal relationship between the accumulation of polyacetylated histones in the presence of *n*-butyrate on the one hand, and the inhibiting of DNA synthesis and the switching of malignant cells to non-malignant differentiating cells on the other.

We thank Professor L. A. Steiner and Erlinda Capuno for assistance with the amino acid analyses, and Barbara Blanchard for technical assistance. The Friend erythroleukaemia cells were grown in Professor David Housman's laboratory; the help of Virginia Weeks is gratefully acknowledged. This work was supported by grants from the US NIH (AM 13945).

Yeast virus-like particles possess a capsid-associated single-stranded RNA polymerase

MANY species of fungi possess virus-like particles with double-stranded RNA (dsRNA) genomes[1,2]. In yeast the dsRNA genome has been shown to be the genetic determinant of the 'killer' character[3–10]. No cycle of lysis and reinfection has been demonstrated for 'viruses' of this group and replication is integrated with host growth[1,2]. Particles from several species of fungi have been shown to possess RNA polymerase activity and we have shown that yeast particles isolated from growing cells synthesise dsRNA (refs 11–14). We report here that particles isolated from non-growing cells synthesise both dsRNA and a single-stranded (ssRNA) species with properties suggesting that it is a complete transcript of the dsRNA genome. Our results with particles from growing cells suggested that the replicative cycle of yeast 'virus' resembles that of reovirus[14] and does not occur through the 'doubling cycle' which was put forward by Buck[13] to account for his results with *Penicillium stoloniferum* S. virus. The discovery of a ssRNA polymerase activity in yeast particles is consistent with the reovirus type of replicative cycle.

Particles were prepared from stationary phase cells of the strain 3/A1 (ref. 3) which possesses only P1 dsRNA and were incubated in the RNA polymerase reaction mixture as described in the legend to Fig. 1. The RNA reaction product was isolated and separated into ssRNA and dsRNA fractions by chromatography on cellulose[14,15]. These fractions were analysed by polyacrylamide gel electrophoresis (Fig. 1). Incorporation was found in both fractions but only 4%

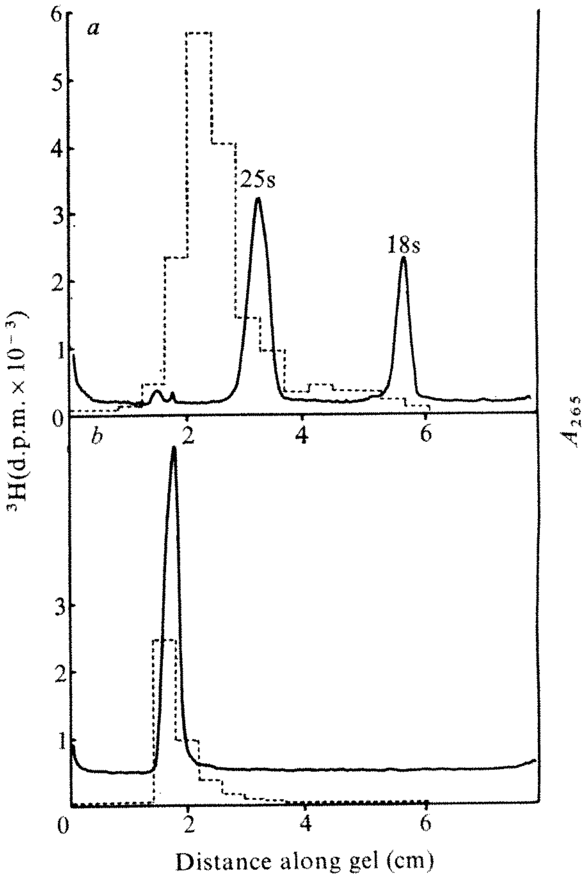

Fig. 1 Analysis of the ssRNA polymerase product on 2.6% polyacryladmide gels[27]. Yeast VLPs were prepared from strain 3/A1 after 10 d of culture by disruption of the cells with glass beads followed by polyethylene glycol precipitation of the VLPs (ref. 21) and isolation by differential and sucrose gradient centrifugation[1]. 2.9 A_{260} units of VLPs were incubated at 30 °C for 125 min in 0.7 ml of 0.05 M Tris-HCl buffer (*p*H 7.9) containing 0.15 M KCl; 0.1 mM EDTA; 3.0 mM $MgCl_2$; 0.20 mMGTP; 0.20 mM ATP; 0.20 mM CTP; 0.20 mM ^{3}H-UTP (330 mCi $mmol^{-1}$) and bentonite (2 mg ml^{-1})[13]. RNA was prepared by addition of 2 volumes of 0.05 M Tris-HCl containing 0.1 M NaCl and 2% tri-isopropylnapthalene sulphonate followed by two extractions with phenol and alcohol precipitation with 100 µg of yeast tRNA as carrier. CF-11 cellulose chromatography[15,16] was used to separate the ssRNA and dsRNA followed by reprecipitation and analysis on gels. Figure 1*a* shows the A_{265} (solid line) and radioactivity profiles (dotted line) of a gel loaded with 1/7th of the total ssRNA product from the reaction mixture described above plus 30 µg of total yeast nucleic acid. Figure 1*b* shows similar profiles for the total dsRNA loaded on to the gel after digestion with ribonuclease A (1.0 µg ml^{-1}) in 1×SSC (0.15 M NaCl, 0.015 M Na citrate, *p*H 7.0) for 10 min at 17 °C. The radioactivity profile was obtained by slicing the gel into 4-mm slices, digesting the slices with 0.5 ml H_2O_2 overnight at 60 °C and scintillation counting after addition of 5 ml of scintillation fluid (Nuclear Enterprises NE 250) to each vial.

of the counts were found in dsRNA. The major ssRNA product migrates as a single species with an estimated molecular weight of 1.6×10^6 relative to yeast ribosomal RNA standards[16]. This value is in good agreement with the estimates of the molecular weight of denatured P1 dsRNA obtained by polyacrylamide gel electrophoresis in formamide, which were 1.60 and 1.63×10^6, but is not consistent with our reported estimate of 2.5×10^6 for P1 dsRNA, estimated from aqueous gels[16]. The molecular weights of the *Aspergillus foetidus* S. virus dsRNA, however, which we used as standards have been re-estimated as 4.0×10^6 and 2.5×10^6 (personal communication from K. W. Buck and G. Ratti). This has enabled us to revise our molecular weight estimate for P1 dsRNA to 3.3×10^6. This figure agrees well with the formamide gel data.

The inclusion of bentonite in the reaction mixture is necessary to eliminate contaminating ribonuclease activity[17]; without bentonite the ssRNA product was found to be of low molecular weight. Because a low molecular weight product was found when VLPs from growing cells where incubated without bentonite[14] it is probable that they too possess ssRNA polymerase activity.

The gel profile of the dsRNA labelled in the reaction differs from that made by VLPs from growing cells in that it was of normal genome size and its mobility was unaltered by ribonuclease digestion (undigested sample not shown). This can be explained in three ways· it may be the result of the completion of short unreplicated ssRNA 'tails' on dsRNA molecules, as suggested for the dsRNA polymerase activity found associated with bacteriophage Φ6 virions[18]: it could be produced by a doubling reaction in which a small proportion of the ssRNA transcripts become templates for the dsRNA polymerase as is thought to occur in *P. stoloniferum* S. particles[13]: or it may be that the mechanism of the transcription reaction is not completely conservative as in reovirus[19] but semi-conservative with the ssRNA product being produced by strand displacement This latter mechanism is thought to operate *in vivo* during the replication of bacteriophage Φ6 (ref. 20). We are attempting to distinguish these alternative mechanisms experimentally.

The first report of a fungal virus polymerase producing ssRNA was from Ratti and Buck[21], who found that 70% of the *in vitro* product formed by particles of *Aspergillus foetidus* S. virus was sensitive to ribonuclease while the remainder was resistant and was assumed to be dsRNA. If the mechanism of the transcriptase reaction is strand displacement, the ratios of ds to ssRNA synthesised both in yeast and *Aspergillus foetidus* particles suggests that only in a few active particles which can initiate several rounds of synthesis does the reaction occur.

That the 1.6×10^6 molecular weight ssRNA product is a faithful transcript of the P1 dsRNA genome was substantiated by the hybridisation data shown in Fig. 2. The annealing conditions used, which are described in the legend to Fig 2, are based on those of Kielland-Brandt and Nilsson-Tillgren[22]. An excess of unlabelled P1 dsRNA was denatured and reannealed in the presence of ssRNA polymerase product. The renatured RNA was digested with ribonuclease and analysed on polyacrylamide gels. Fig 2*a* shows that the peak of activity and the peak of accurately renatured dsRNA coincide in the gel, that is, the ssRNA product is very near to half genome size as is the case with reovirus transcripts hybridised to genome dsRNA (ref. 23). The trailing shown by the peak of activity down the gel was also seen when the gel was stained although it is not very clear from the A_{265} profile. It is due to the heterogeneous population of dsRNA molecules which are generated by the digestion of network structures formed during the annealing[23]. Figure 2*b* shows a control sample which was not subjected to denaturation but was simply incubated at the annealing temperature. No activity is found on the gel which confirms the ribonuclease sensitivity expected of ssRNA and shows that it does not form ribonuclease resistant dsRNA by a process of self-annealing. The ssRNA product thus seems to be a transcript of a single strand of the dsRNA.

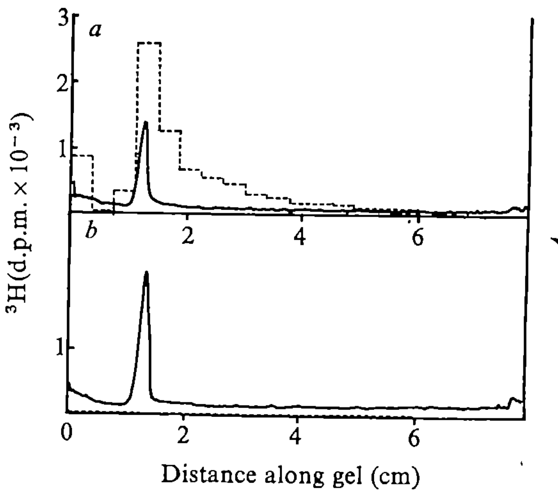

Fig. 2 Hybridisation of the ssRNA polymerase product. Polymerase product was taken up in 2.0 ml of 1×SSC containing 45% (v/v) formamide and 20 μg of unlabelled Pl dsRNA. The sample was divided equally, sample (*a*) was heated to 85 °C for 3 min and then incubated at 60 °C for 30 min, sample (*b*) was incubated at 60 °C for 33 min Both samples were precipitated with 2 vol. of ethanol after the addition of 100 μg of tRNA as carrier and loaded on to 2.6% polyacrylamide gels[27] after a 10 min digestion with ribonuclease as described for sample (*b*) in Fig. 1. Electrophoresis was for 6.5 h at 3.8 mA per tube. A_{265}, solid line; radioactivity, dotted line.

The amount of input ssRNA entering hybrid was calculated from the results of a separate experiment at 69%. This experiment included a sample which was neither denatured nor ribonuclease-digested. The degree of renaturation in this experiment, calculated by a comparison of the area of the dsRNA peaks in the A_{265} profiles, was found to be 65%.

The data together with our previous results show that both the polymerase activities required to undergo the asynchronous cycle of replication utilised by reovirus[19] are found in the yeast VLP. Bruenn and Keitz[24] have shown recently that yeast dsRNAs lack the 7-methyl guanosine 'cap' structures which are found both at the 5′ end of the + strands of reovirus dsRNAs[25] and in yeast mRNAs (ref. 26). They have suggested that this indicates that replication does not proceed by the reovirus cycle. We are investigating the *in vitro* methylation of the ssRNA polymerase product together with other aspects of its structure and synthesis.

We thank K. B. Buck and G. Ratti for advice and discussion and G. Foster for technical assistance. This work was supported by a SRC grant to E.A.B.

Enzymology in supercooled water

Recent years have witnessed an increasing interest in applications of low temperature techniques to studies of enzyme-catalysed reactions, the aims being the temporal resolution of the contributing reactions and the stabilisation of intermediate species. To overcome the low temperature limit set by the freezing point of the aqueous medium mixtures of water and various polar organic solvents have been used[1–4]. Although these aqueous mixtures affect the solvation interactions of the enzyme and its conformational stability[5], they can be shown to influence neither substrate specificity, nor the reaction pathway. We have investigated the feasibility of supercooled water to achieve conditions closer to the physiological ones. To circumvent freezing by heterogeneous nucleation, the aqueous phase containing enzyme, substrate and buffers was emulsified in an oil which was supersaturated with a water insoluble surfactant[6]. We here present the results on bacterial cytochrome P_{450}, a mono-oxygenase which has already been studied in mixed solvents[1,2]

Sorbitan tristearate was added to corn oil or safflower oil at 2.5% (w/v) and dissolved by gentle heating. An aliquot (1.5 ml) of an aqueous solution containing the enzyme in phosphate buffer, KCl and camphor (substrate) was emulsified in 3.5 ml of the oil phase at 10 °C. This was achieved by manual shaking, followed by microemulsification in a blender, until a droplet size of 1–5 μm diameter had been obtained. Optical spectra were recorded at temperatures down to −30 °C using an Aminco–Chance DW2 spectrophotometer. The various redox states of the substrate bound enzyme could be observed at low temperatures. The equilibrium constant governing the spin state equilibrium of the ferric cytochrome P_{405} was measured at several temperatures. The Van't Hoff ΔH at pH 7 agreed well with the corresponding value at ambient temperatures (10.3 kJ mol^{-1}) (ref. 7) but differed significantly from the low temperature value (30.1 kJ·mol^{-1}) determined in a 50% aqueous ethylene glycol solution[8].

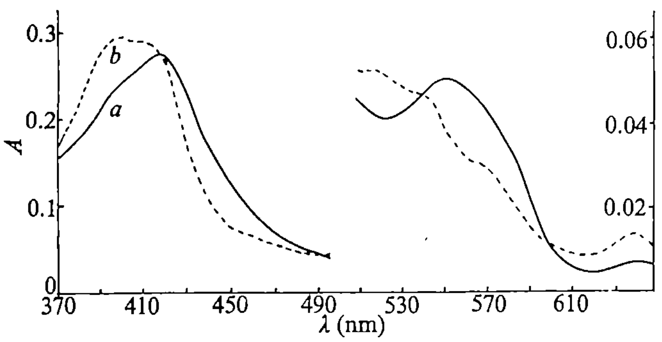

Fig. 1 Spectra of (*a*) oxy-ferrocytochrome P_{450} ($\mathrm{Fe_S^{2+}.O_2}$) stabilised at −20 °C in emulsified supercooled water, and (*b*) the same sample after warming and maintaining at 20 °C for 40 min and subsequently recooling to −20 °C. The long wavelength part of the spectrum (right-hand ordinate) was recorded with a higher sensitivity.

To investigate the possible stabilisation of labile species at subzero temperatures the unstable compound P_{450} ($\mathrm{Fe_S^{2+}.\ O_2}$) was formed at 0 °C, quickly emulsified and cooled to −20 °C in the spectrophotometer. The absorption spectrum in Fig. 1 clearly shows the maxima at 418 and 552 nm, characteristic of the oxy-ferrocytochrome. Repetitive spectra taken over a period of 1 h showed no evidence of autoxidation. After heating the emulsion to 25 °C for 20 min and recording another spectrum at −20 °C, the compound had been totally transformed to $\mathrm{Fe_S^{3+}}$. All spectra recorded in supercooled water were identical to those observed in normal conditions, except for a low temperature-induced sharpening of the peaks.

The preliminary experiments indicate that the extension of the accessible temperature range to the homogeneous nucleation temperature (approximately −40 °C) permits the stabilisation of enzyme-substrate complexes, and of labile intermediates and makes possible the temporal resolution of the enzyme catalysed reaction. A more detailed account of this work is in preparation.

Corrigenda

In 'Lead isotope measurements from the oldest recognised Lewisian gneisses of north-west Scotland' by H. J. Chapman and S. Moorbath (*Nature* **268**, 41; 1977), line 4 in paragraph four should read . . . The isochron yields an age of 2680±60 Myr (2σ), which . . . .

In 'Eighty thousand β-adrenoreceptors in a single cell' by D. Atlas, F. Hanski, A. Levitski (*Nature*, **268**, 145; 1977) the ordinate label of Fig. 1*c* should read . . . ($\mathrm{M^{-1}\times10^{-14}}$).

In 'Histone content of germinating pea embryo chromatin decreases as DNA replicates' by F. Grellett, M. Delseny and Y. Guitton (*Nature* **267**, 724; 1977) the labelling of the peaks in Fig. 1 should read (from left to right): H1 (30,500; 26,500; 24,800), H2B (16,800), H2A (15,100), H3 (13,500), H4 (10,500).

reviews

A zoophile's testament

Eric Ashby

The Moral Status of Animals. By Stephen R. L. Clarke. Pp. 221. (Oxford University : Oxford and London, 1977.) £5.95.

In fairness to the author of this book, it must be said that he is a professional philosopher and this reviewer is not. And in fairness to this reviewer it must be said that the book is not addressed to philosophers but to the public at large. Moreover, it is not written to inform : it is written to persuade, with an uncompromising vehemence unusual among philosophers. So Dr Clark has to put up with the fact that I'm not competent to comment on the subtleties of his logic, just as I have to put up with Dr Clark's assertion (p183) "that no-one has any standing" in discussing the theme of his book "who has not taken the simple, minimal step of abandoning flesh-foods."

For that is the demand—and 'demand' is not too strong a word—which Dr Clark makes upon the reader. "I am a committed crank and zoophile, and my hope is to convert my audience." "Those who still eat flesh when they could do otherwise have no claim to be serious moralists." Dr Clark is fully aware of the consequences which would follow if his mission were to succeed. There would be a phasing out of all animal husbandry, from sheep and poultry, to fisheries and (presumably) shellfish beds. The sight of sheep placidly grazing is offensive to Dr Clark; they are the innocent and unaware "inmates of our Belsens" (p80). If this seems immoderate and emotive language from the pen of a philosopher, Dr Clark defends himself with the statement : "I am very much more interested in achieving a practical issue than in the details of abstract philosophy, and am willing to argue on almost any basis to achieve that end." But even this defence does not excuse such nonsense as the assertion (p188) that "flesh-eaters pretend that their victims delight to serve them."

Of course, abstinence from all flesh foods is only one of the demands which Dr Clark makes upon us. There must also be abstinence from all vivisection and from the use of animals to test drugs, on the ground that we must not do to animals anything which we would not legitimately do to human beings.

The book is written in a learned, not to say pedantic style, with copious references to authorities from Porphyry in the third century AD to Roszak in the twentieth century. Dr Clark professes himself to be a Christian but he confesses to finding little support for his thesis in the Bible and he is embarrassed by Christ's participation in the catching of fish. He admits that there is some sort of hierarchy among living creatures—to murder a sheep is "perhaps in less degree" serious than to murder a shepherd—and he is evasive about insects, although he admits with reluctance (p82) that insects killed on impact with a car windscreen weigh "less heavily than a deliberate killing."

There is an appendix with advice on vegetarian cooking.

This is a deeply disappointing book, for the issues which Dr Clark discusses are important. A critical examination of them would be timely because—contrary to numerous reckless assertions in Dr Clark's book—the common man *is* aware as never before of his kinship with the rest of nature. No-one who has seen nature films on TV believes (as Dr Clark implies on p37) that animals are stupid; no-one doubts that they suffer pain, can be apprehensive of danger, and that many kinds of animals are capable of affection, not only within their species but even toward man.

The widespread empathy between human beings and the rest of the natural world creates an interest in the rights of animals. A careful and sober enquiry into the consequences of this empathy would be welcome. Any such enquiry would have to take into account three considerations, none of which Dr Clark has faced squarely.

First, if as Dr Clark admits, the intensity of concern diminishes as one passes from mammals to vertebrate and from vertebrates to insects, where does it stop? And if not at insects, why not include plants? (Christopher Stone has already written an essay, far more persuasive than Dr Clark's, on the question whether trees should have standing in the law-courts of America.)

Secondly, Dr Clark admits that it's not our business to save the rabbit from the fox or the fly from the spider, but he does not explain why man, as an integral unit in nature, should abdicate from the place he has occupied in the food chain for millennia. Hamlet's "We fat all creatures else to fat us and we fat ourselves for maggots . . ." is a curt but accurate summary of man's place in the biosphere.

Finally, much of Dr Clark's case rests on the premise that man must not treat animals with less concern than he treats his fellow men. In fact man treats animals with more concern: we may kill domesticated animals in order to eat them; we don't torture them because they do not share our political or religious ideologies. The intraspecific behaviour of animals to one another is, by and large, more compassionate than our own intraspecific behaviour. ☐

Eric Ashby (Lord Ashby of Brandon) is Walgreen Professor of Human Understanding at the University of Michigan.

Cell surface in embryogenesis

Cell Surface Reviews. Volume 1: The Cell Surface in Animal Embryogenesis and Development. Edited by George Poste and Garth L. Nicholson. Pp. 766. (North-Holland: Amsterdam, New York and Oxford, 1977.) $89.95; Dfl.220.

This is the first in a new series of volumes designed to collate literature on cell membrane research. Three more volumes (Virus Infection and the Cell Surface, Dynamic Aspects of Cell Surface Organisation, Membrane Assembly and Turnover) are promised within the year. After this, volumes will be added to the series annually. This book deals with the more general aspects of development.

The chapter by Trinkaus is a scholarly survey of cell movement. Widely held misconceptions are exposed and corrected. Arnold's review on cytokinesis is concise and lucid.

Cell communication is discussed in four of the reviews. Sheridan provides circumstantial evidence for gap junctions as a structural basis for low resistance coupling of cells. Uncoupling of cells in development may prove to be an exciting clue to the mechanism of control. Aspects of differentiation relating to cell or tissue position are examined in a splendidly iconoclastical spirit (McMahon and West) in both regulating and non-regulating systems. Most of the important research dealing with embryonic induction has been compiled by Saxén *et al.* Cell surface specificity in cell systems *in vitro* seems to be present (Maslow), but its relevance to actual developmental events can always be questioned.

Five of the reviews deal with the development of the mammalian conceptus and placenta. They might have been more usefully placed in one of the later volumes. Gwatkin restricts his consideration of the organisation of the cell surface of gametes to the mouse. This seems a pity since much of the interesting work in this field lies in invertebrate studies. Sherman and Wudl make provocative comments about the putative role of the blastocyst in implantation. The transport of molecules across placental membranes is lengthily listed (Miller, Koszalka and Brent) and some studies of cell surface antigens in mammalian developments are reviewed by Edidin.

The development in only three organ systems is covered, and in each a somewhat pedestrian note is struck. Hot or controversial issues have not been stirred up in these reviews about the heart (Manasek), limb bud (Ede), or immune system (Goldschneider and Barton).

All in all, the editors and reviewers have done a fair job. The publishers, however, can be severely criticised. The book costs ninety dollars, has many typing errors and is inadequately indexed. I have recommended this book to our library, but they cannot afford it.

Joan Feldman

Joan Feldman is a Research Fellow in Zoology at University College, London, UK.

Solar planets

The Solar Planets. By V. A. Firsoff. Pp. 184. (David and Charles: Newton Abbot, London and Vancouver; Crane, Russak: New York, 1977.) £5.50.

CRUDELY one can divide science books into four categories, elementary and advanced, good and bad. Firsoff's book is elementary and bad.

There is nothing wrong of course with a book being elementary. This one is written for the amateur astronomer and purports to be a study of the Solar System written in the light of the wealth of new knowledge gleaned from the unmanned space probes which have recently visited Mercury, Venus, Moon, Mars, Jupiter and Saturn. True, the book contains plenty of details about these missions, seventeen black and white plates and no formulae. And obviously the book is not all wrong, in fact a good 95% is right, but the unsuspecting reader has no way of picking out right from wrong, fact from the authors' flight of fantasy, the solid ground from the castles in Spain.

We are told: "it seems that the Moon began its existence as an independent planet and was later captured by the Earth", "a limestone meteorite fell in 1926 at Bleckenstad and is said to have contained fossils", "Pluto may possibly belong to an older solar system or else be an immigrant from interstellar space"; "degeneracy is a condition derived from equations based on various simplifications which are always suspect". "I am not too sure that even in the Solar System ours is the only technical civilisation", "geography is fast becoming only a division of astronomy"; "fissile radioactive materials could become concentrated by geological processes into a natural atomic pile, which could occasionally blow up", and a host of other *non sequiturs.* Many facts pop out at us like rabbits from a hat accompanied by a similar aura of surprise and lack of explanation. The book also uses jargon freely. The reader, having no glossary, has to turn to other works for definitions of such terms as Hohmann transfers, coriolis force, grey-sphere radiative equilibrium, body tides, bond albedo and so on. Also in evidence is Firsoff's dislike of professional scientists. For example, "the idea of an inert Moon is still widely held among scientific officialdom, often in the teeth of overwhelming evidence against it". In discussing a dark pattern seen on one of the rocks on Venus pictured by Venera 9 Firsoff puts forward the idea that this could be a lichen growth—a genus from a high temperature biology based on sulphuric acid as the solvent: "of course this is speculation" Firsoff writes, "and speculation is a dirty word in professional circles—but many of the hypotheses that have been given an official accolade are even less well founded".

This book gives an entirely wrong impression of present knowledge of the Solar System and of the state of mind of the scientific enquirer who is presently investigating the planets. Not only do I advise people not to buy this book, I will go further, don't even bother to open it.

David W. Hughes

David W. Hughes is Lecturer in Astronomy and Physics in the Department of Physics at the University of Sheffield, UK.

Pursuit rotor performance

Remininiscence, Motivation and Personality. A Case study in Experimental Psychology. By H. J. Eysenck and C. D. Frith. Pp. xxi+430. (Plenum: New York and London; 1977.) $33.

THIS self-proclaimed "case study in experimental psychology" is concerned exclusively with the phenomenon of reminiscence as observed in studies of pursuit rotor performance. The pursuit rotor is a piece of apparatus which requires a human subject to keep a stylus in contact with a small target on a rotating turntable. The reminiscence effect refers to a gain in performance—and possibly in learning—when a rest period is introduced after a period of practice. The authors' introduction asserts that "whether the accumulated work done by generations of students on the problems discussed in this book has been worth the trouble must be left to the reader to judge." The authors are presumably optimistic about the reader's verdict; but not, I think, with good reason.

The major virtue of the pursuit rotor is said to be the replicability of the data which it generates—"perhaps the most reliable set of observations in experimental psychology." The pursuit rotor, we are told, is "the psychologists' favorite piece of apparatus." These claims seem absurdly parochial, but even if taken seriously they are offset by the authors' remark—in criticising a study which disagrees with their views—that "the literature on reminiscence is especially rich in 'failures to replicate.' "

The book does, however, provide a detailed history of research on this narrow problem. The same studies which the authors had earlier interpreted in terms of "inhibition" theory are now interpreted in terms of "consolidation" theory. The fit of the new theory to data, like that of the old, is not so striking as to compel belief. The theoretical concepts used have not arisen from the study of reminiscence in the pursuit rotor task, but have been imported from general psychology. There is no shortage of available 'explanatory' concepts.

This work will be of interest, and possibly of value, to those who are concerned with the pursuit rotor and related matters. There are, however, many experimental psychologists who would have preferred a more fertile subject for such extensive case study.

Leon J. Kamin

Leon J. Kamin is Professor of Psychology at Princeton University, New Jersey.

Regge theory

An Introduction to Regge Theory and High Energy Physics. By P. D. B. Collins Pp. xiii+445. (Cambridge University: Cambridge, London and New York, 1977.) £29.

OVER the past fifteen years, the theory and phenomenology of high energy collisions of strongly interacting particles have developed into a powerful and coherent picture The basic idea is a subtle generalisation of Yukawa's idea of forces being due to exchanges of particles. This idea is, of course, built on the classic example of electrodynamics, where exchange of photons provides the electromagnetic forces between electrons. When this idea is applied to the exchange of known strongly interacting particles of high spin it leads to absurdities in specific kinematic regions. The classic mathematics of Regge and its applications by Chew, Frautschi, Mandelstam and others was that an object called a Regge pole could be usefully defined, which subtly changed from being one particle into another for different kinematics. Thus, exchange of a Regge pole is equivalent to exchange of many Yukawa particles in a simple way. The Regge pole also clearly serves to classify the several (many?) particles whose exchange it controls. These particles all have different spins. Thus, it provides a classification of a totally different nature to the canonical isospin, strangeness (SU(2) and SU(3)), beloved of group theorists, which classifies objects of the same spin.

This theory has been developed and tested in a wide variety of collision processes and has encountered no conspicuous disasters in confronting the data. The status of experiment and theory in this field are superbly reviewed by Dr Collins in this elegant book. The level is beautifully judged to lead a new research student into the depths of this field and start him on his research career. On the other hand, as a worker in this field, it gave me great pleasure to see the material laid out so coherently. The book contains a judicious amount of data without which one can so easily become lost in the theoretical intracacies.

After a quick introductory review of the basic assumptions of scattering theory, Dr Collins turns to the fundamental derivations of the complex angular momentum plane and models which show the existence of Regge poles. The basic Regge trajectories are then discussed and the connection with internal symmetry groups brought out in detail. These trajectories are found from fitting the data. The details of these fits are admirably described.

Because of analyticity, if we know the high energy behaviour of scattering amplitudes, strong constraints are imposed by Cauchy's theorem on the low energy amplitudes. These constraints are typically given by the so-called finite energy sum rules and duality. These are again succinctly described by Dr Collins.

In a relativistic theory it is known that as well as the Regge poles to be exchanged there are so-called 'Regge cuts' which come from exchange of two Regge poles. These correspond to re-scattering cross-sections in the manner of Glauber theory. This is an area of great theoretical interest in view of the rising total cross-sections found at the CERN intersecting storage rings using the highest available energies This chapter is followed by a discussion of the ingenious way in which Regge poles contribute to collisions with three or more particles in the final state. In particular, the application to inclusive processes where, say, two protons collide to turn into a pion plus an unknown number of other final state particles, is described in detail. This is a true success of the theory in a fundamentally relativistic situation, with many particles being produced out of pure energy.

Finally, the relatively unsuccessful attempts to calculate the Regge trajectories from more fundamental theories are described. This joins naturally to the last chapter which connects with conventional field theories and their Regge trajectories. A brief discussion of deep inelastic electron–proton scattering is given, with its hint that there may be point constituents in protons, unlike the fuzzy picture suggested by Regge theory.

In conclusion, this is a superb introduction to strong interaction dynamics with an admirable blend of theory, speculation and experimental data which I cannot recommend too warmly.

I. G. Halliday

I. G. Halliday is Reader in Theoretical Physics at the Blackett Laboratory, Imperial College, University of London, UK.

Mercurial chemistry

The Chemistry of Mercury. Edited by C. A. McAuliffe Pp. 288 (Macmillan: London, 1977.) £25.

WHILE reading this slim volume one is conscious of the fact that each page costs just under 10p and it is thus rather annoying to find that 29 pages are completely blank, contain only titles or are less than half full.

Unhappily the book falls far short of its title; certainly it is not a treatise on mercury as claimed in the Introduction. There is no attempt made to compare mercury with its congenors or with the the alkaline earth elements, and the aqueous chemistry of Hg^{2+} is dismissed in the eight lines of "chapter" 17. I had hoped that one could have picked up this book and had the whole of mercury chemistry at one's finger tips but, since the style of the main chapters is somewhat similar to that of the *Annual Reports of the Chemical Society,* access to a good library is essential to obtain sufficient background knowledge. Although "to avoid duplication, work presented in recent reviews is not duplicated here", there is considerable overlap in Chapters 11 through 17 with Professor Aylett's article (about 1969) in Pergamon's *Comprehensive Inorganic Chemistry*—indeed, in several places the two descriptions of Hg_2^{2+} and Hg^{2+} chemistry, necessarily, read almost word for word; naturally this book contains a little more up-to-date material (May, 1975). I looked for, but did not notice, any mention of Aylett's review among the copious references.

The first part of the book gives a readable account by Farrar and Williams of the history of mercury, but takes up 45 precious pages; numerous quotations from translations of Pliny and alchemical texts are presented. Part two by Levason and McAuliffe discusses the coordination chemistry of Hg_2^{2+} and Hg^{2+}. The organic chemistry of Hg (II) is dealt with in considerable detail by Bloodworth in Part three, and the biochemistry and toxicology of mercury (Falchuk, Goldwater and Vallee) are dismissed in a disappointingly brief section considering their current intense interest.

There would seem to be no justification for a short book of this title, and certainly the price will keep it out of the reach of all but the most dedicated of mercury chemists and the well-endowed libraries. On reading the title I had high hopes as to the contents but these hopes were largely shattered as it became clear that the book was meant as a review and not a readable and critical account of this most unique element. Approximately two dozen actual printing errors were noticed, whereas broken type occurred with too high a regularity for a book in this price range.

A. G. Massey

A. G Massey is Reader and Head of Inorganic Chemistry at Loughborough University of Technology, UK.

Structure and properties of the solid surface

The Chemical Physics of Surfaces. By S. Roy Morrison. Pp. xii+415. (Plenum: New York and London, 1977.) $47.40.

SURFACE STUDIES constitute a substantial growth area in contemporary scientific research. During the past decade or so, a host of new techniques have provided insights into the structure and properties of the solid surface. These developments in turn have had a bearing on those technologically important processes where surface interactions are important—in solid-state devices, in oxidation, in corrosion and in catalysis.

In the past four years, several small monographs have appeared on the structure of the solid surface (Oudar, Blakely, Samorjai, Prutton); in those cases where reactions have been considered, however, they have been treated largely in terms of the atomistic nature of the surface. The present book attempts to re-dress the balance by emphasising the electronic band structure of the surface and the role of surface states in determining the interaction of the surface with a gaseous or liquid environment. The book is thus aimed primarily at those interested in surface chemistry and tends to deal more with semiconductors than with other types of solid.

The author expresses the hope that the book will also appeal to the mature surface physicists but it seems to me that it is too specialised and that it lacks more figures of the type given in Figures 5.1 and 5.2, where the lobes of orbitals and so on are of particular assistance to the non-chemist, and a few more energy diagrams illustrating the electron or hole switching mechanisms would clarify some of the verbal accounts of surface interactions.

Again, the references (almost 1,000) cover mainly the period from 1970 to 1975. The book is thus essentially a concentrated review of the more important papers published over a relatively short period. As such, it is indeed a tribute to the author's encyclopaedic knowledge and understanding of recent work involving general aspects of surface interactions, especially in relation to semiconductor surfaces. It does, however, carry with it certain limitations. For example, because of Dr Morrison's overwhelming interest in catalytic processes and in the chemical properties of ionic and semiconducting solids, his account of surface interactions gives only passing reference to faceting and little more to the role of surface defects.

One of the most exciting (and perhaps depressing) features of surface science is the rate at which new techniques are continuously emerging. Dr Morrison's book deals with papers up to the end of 1975 and quotes ultraviolet photoelectron spectroscopy (UPS) as "the most important tool of the surface spectroscopies in providing us with information on surface states and adsorbate bonding". Since then, high resolution energy loss spectroscopy (HRELS) at extremely small electron energies has appeared on the scene and has shown that it is possible to detect the vibrational characteristics of adsorbed atoms or molecules. It thus promises to provide more direct information than UPS about the location and bonding of surface species. No doubt in two years' time it will be superseded by yet another technique. This is not, of course, a criticism of Dr Morrison's monograph. His book is a treasury of information and an essential acquisition for any laboratory engaged in surface studies involving catalysis and solid–gas or solid–liquid interactions, especially of semiconducting solids.

David Tabor

David Tabor is Professor and Head of the Physics and Chemistry of Solids Research Group at the Cavendish Laboratory, University of Cambridge, UK.

Broad geophysical canvas

Our Changing Planet. By John Gribbin. Pp. 165. (Wildwood House: London, 1977.) £5.95.

THIS small book is intended to persuade laymen of the importance of geophysical research to Man's present needs, and also of its intrinsic interest. It ranges over a broad canvas, including the origins of the Solar System, oil, gas and metals, the possible relationship between sunspot activity, climate, biological evolution, and earthquakes, as well as the inevitable plate tectonics. This hotchpotch hangs together moderately well and avoids the doomwatch approach which often characterises such publications. The book is also well produced, with a pleasant appearance, a short layman's bibliography and an index. To complet the credit score, the number of printer's errors are few and these are amusing rather than annoying—larval plains on Mars, for example.

After commenting favourably on its readability, however, the credits become largely exhausted. The glib tone tends to be combined with an inadequate presentation, occasional misrepresentation and even straight errors. The importance of continental shelves as potential oil fields is clear enough without claiming that the Siberian Artic continental shelf is larger than Africa, and the English Channel does not immediately jump to mind as exemplifying the characteristics of the shallow seas in which oil deposits are laid down. Greek ideas on the cause of earthquakes, dismissed as silly, still seem appropriate in particular conditions, such as those at Agadir. Some arguments are seriously neglected, such as the isotopic information for the origin of the metal brines of the Red Sea, and others seem almost topsy-turvy.

Earth expansionists use the 'improved' fit of the continents on a smaller globe as part of their evidence in favour of expansion yet Gribbin sees the fit as a clear argument against. Although this reviewer's feelings about expansion make him side with Gribbin on this, the lack of evidence for expansion on the Moon, Mars, Venus, and so on, are the more telling arguments and are ignored.

It is also somewhat distressing to find, apparently, how provincial geologists are, compared with geophysicists. Apparently, geologists are concerned only with the status quo, and it is geophysicists who are concerned with the changing Earth. Although such cynical comments can be made only too easily, the most serious drawbacks for the lay reader, however, must be the lack of adequate illustrations and of clear exposition as to what, for example, plate tectonics is. If the initial picture had been presented more clearly, then one could almost, but not quite, forgive some explanations—for instance, how can North America override a spreading ridge? Simply because the Atlantic is spreading westward faster than the Pacific is spreading eastwards! In many cases, the glibness overtakes the information which is necessary, even for the lay reader. The Chandler Wobble, for example, is described as the pole dancing around, in stately fashion, relative to the stars, but the uninitiated will want to know the scale of this dance—is it confined to a barn, a ballroom or a continent?

I am sorry that I cannot recommend this book to anyone, which is not merely unfortunate but depressing. If John Gribbin had spent much longer on its preparation and confined himself to only two or three topics, it could have been excellent—but he didn't.

D. H. Tarling

D. H. Tarling is Senior Lecturer in the Department of Geophysics and Planetary Physics at the University of Newcastle upon Tyne, UK.

obituary

Sir Landsborough Thomson

Bassano Studio

ARTHUR LANDSBOROUGH THOMSON died on 9 June 1977 at the age of 86. With his death we have lost the last of that small group of men who, in the early years of this century, brought into being the organisation in this country for the national support of scientific research. A noted biologist, with a natural talent for administration, he combined in his own person the qualities required for translating scientific policy into administrative practice. It was, therefore, fortunate that circumstances brought him, at an early stage in his career, into the position of chief of staff at the headquarters of the then embryonic Medical Research Council.

Born in Edinburgh in 1890, Thomson spent his formative years in Aberdeen where his father was Regius Professor of Natural History. After graduating as MA in 1911, he elected for an academic career in zoology. In preparation for this, it was decided, in line with the spacious traditions of those days, that he should first broaden his education. So he went to study, first at Heidelberg, and then in Vienna from where he only just succeeded in escaping before the outbreak of the First World War.

Arrived back in Scotland, he immediately joined the Argyle and Sutherland Highlanders. With that distinguished regiment he went to France and saw hard service. It was then that his flair for administration first revealed itself. As a result he was recruited to the staff and ended the war, in the rank of Lieutenant-Colonel, as an Assistant Quartermaster-General at General Headquarters. He thus came to take a different view of his future. Returned to civilian life, he went to the Treasury. But he was only there for a short while. Sir Walter Fletcher, the then Secretary of the Medical Research Council, was looking for a man to build up the administrative side of his organisation; and Thomson was the obvious choice for the post.

When Thomson joined the MRC the entire staff at headquarters, apart from the Secretary, numbered no more than half-a-dozen persons. When he left, some forty years later, the figure was 130. Nevertheless, even then, the staff was remarkably small when set against the size of the Council's organisation and the scope of its activities. In part this was due to its having grown naturally rather than as a result of reforms imposed from outside. More especially, however, it was due to Thomson's wide range of capabilities. With his scientific background, and his continued personal involvement in research in ornithology, he was never in danger of mistaking means for ends and complicating administrative procedures accordingly. For him the first task was to identify the scientific requirements of any given problem and then devise measures for meeting these. Not that he ever fell into the opposite error of ignoring those basic principles and methods that are applicable to all administration, whatever its purpose. But he required that every case be approached on its merits, never on the basis of precedent. That was the atmosphere that permeated the whole office under his sway. As a result, agreements were reached with the minimum of fuss and, although prospective applicants might go away disappointed, they could seldom, if ever, feel they had been misunderstood.

But Thomson was far more than the head of the Council's machinery for supporting its purely research interests. Having a realistic appreciation of the social and political context in which the Council operated, and a shrewd eye for impending developments, he brought his own expertise to bear on the formation of policies for translating scientific knowledge into practice. An example is the part he played in creating the Public Health Laboratory Service. Originally conceived, in the mid 1930s, as a defence against bacterial warfare, this quietly came into being on the outbreak of the Second World War. Such things do not happen by accident. They are the fruit of realistic vision and informed understanding by those responsible for planning the logistics of such an operation. In the event, the threat this particular service was devised to counter never materialised, but the network of laboratories it provided proved so useful in extending our control over the ordinary infections of civilian life that it was put on a permanent footing and eventually transferred, as a going concern, from the Council to the National Health Service. That Thomson should have been accepted without question as chairman of the expert board which directed such a service, is a sufficient indication of how he was regarded by the scientific community. When I want the MRC, I was exceptionally fortunate in having him as a colleague and mentor, for to work with him was a professional education in itself.

Yet all the time he had another life: that of a distinguished ornithologist. From his earliest years, he had taken an informed interest in wild life. Later, this developed into his classical studies on bird migration. But, at heart, he was always a field naturalist and, in this context, his knowledge was encyclopaedic. Consequently, he was, at one time or other, chairman of all the major organisations for ornithology in Great Britain and, in 1954, President of the XIth International Congress held in Basle. After his retirement from the MRC, his interests in this field could develop freely. He travelled widely, especially in the tropics. He took a major part in the enquiry into the Serengeti Park. From 1954 to 1960, he was President of the Zoological Society of London, from 1964 to 1969, Chairman of the Council for Nature, and from 1967 to 1969, Chairman of the Trustees of the British Museum (Natural History). And, with the help of his devoted wife, he edited his great *New Dictionary of Birds*.

In spite of these commitments, when he came to retire, Thomson readily accepted an invitation from the Medical Research Council to write an account of its development. Having been personally involved in this for most of the period which it covered, he was in a unique position to undertake this task. The outcome, *Half a Century of Medical Research*, is far more than an institutional history. In it he sets out, with characteristic objectivity, the various developments in the British organisation of medical research and the administrative lessons to be learned from these. As such its relevance extends beyond the sphere of its immediate subject to a central problem of the scientific and technological age in which we are now living; namely, that of providing, not only for the development of scientific knowledge, but also for its integration into the machinery of government.

Like his old schoolfellow, Wilson Jameson, the architect of the National Health Service, Thomson understood that for any human institution to be a success, it must satisfy both of two fundamental requirements. It must be in conformity with the realities of that it seeks to organise. It must equally be in conformity with the deeply held sentiments of those who have to make it work. In his own time, Landsborough Thomson contributed his quota to realising these conditions and, thereby, to creating the institutions required if activities that depend on acts of individual judgment are to be integrated into the structure of social organisation. That was the deeper significance of his life's work and his essential legacy to future generations.

Harold Himsworth

Meirion Thomas

Meirion Thomas who died in his eighty-third year on 5 April 1977 at Tywyn in his native Wales will be remembered not only for his academic and athletic prowess but also for sterling personal attributes.

Born in North Wales in 1894, his early academic career as a student of University College of North Wales was interrupted when he was commissioned in the South Wales Borderers in 1914 and later transferred to the Special Companies Division of the Royal Engineers. On demobilisation in 1919 he went to Cambridge (Trinity Hall) where, inspired by his contacts with Gowland Hopkins, F. F. Blackman and Muriel Onslow, among others, he developed interests in plant physiology and biochemistry. He joined the Botany Department in the Newcastle division of Durham University as a lecturer in 1924, became Reader in Plant Physiology in 1942, and in 1946 Professor and Head of the Department where he remained until retirement in 1961.

His book *Plant Physiology,* first published in 1935, brought him to the fore because of its new approach to the subject with its emphasis on the experimental study of plant metabolism. It was reprinted and revised periodically to a fifth edition in 1973, always retaining his aim of educating students in the development of ideas and investigation rather than simply presenting the present state of knowledge. His main research interests as covered by his own publications embraced various aspects of respiratory and acid metabolism with occasional ventures into other fields e.g. melanism, but the sum total of his contributions to science and life could only be assessed by perusal of the long list of students, colleagues and friends who would readily attest that whatever they have achieved, and some have achieved great distinction, they owe much to their contacts at some stage with him.

Meirion Thomas's eminence in science was marked by his election to the Royal Society in 1949. Two other distinctions which gave him great pleasure, and of which he was justifiably proud, were the award of the Charles Reed Barnes Honorary Life-Membership of the American Society of Plant Physiologists in 1963, and the Honorary Degree of D.Sc. of the University of Wales in 1964.

At Cambridge he won a soccer blue and played cricket, being elected to the Crusaders Club in 1923. He continued enthusiastic participation in both with Northern clubs for many years and remained actively interested in them throughout his life. A few years after retirement, his love of Wales, its language, and its cultures drew him to Tywyn, but not as a recluse. He maintained contacts with all his friends, continued to attend scientific meetings and enjoy a full life. He will be remembered with respect and great affection by all who knew him.

S. L. Ranson

A. V. Nikolaev

Academician Anatolii Vasil'evich Nikolaev, a leading Soviet expert in geochemistry and the utilisation of natural resources died on February 13, 1977.

Nikolaev was born in 1902. He graduated from the University of Leningrad in 1924, and soon afterwards became involved in the problems of resource utilisation. From 1927 to 1931 he was head of the Pavlodar Salt Expedition of the Commission to Study Production Resources of the Academy of Sciences of the USSR, and from 1931 to 1935 he headed a similar, combined, expedition to the Kulunda area. Between 1934 and 1957 he worked at the Institute of General and Inorganic Chemistry of the Academy of Sciences in the USSR, and, simultaneously, held various teaching posts in Moscow, at the Polygraphic Institute and the Institute of Non-Ferrous Metals and Gold, becoming a Professor at the latter Institute in 1946. In 1957 he moved to Novosibirsk, to become Director of the Institute of Inorganic Chemistry of the Siberian Branch of the Academy of Sciences of the USSR. The following year he was elected a Corresponding-Member of the Academy of Sciences and a Praesidium Member of the Siberian Branch. He became a full member of the Academy in 1966.

Nikolaev's main works deal with the physical and chemical analysis of salt systems, thermography and radiochemistry. His interests were wide and his published titles reflect this diversity, ranging from *The Kulunda Salt Lakes and means of desalinating them* and *The physico-chemical study of natural resources,* to *Protection against radioactivity,* and *A study of the processes of oxidation of complex compounds of divalent platinum.*

In 1947, he won the Vernadskii prize, and, in 1967, on the occasion of his 65th birthday, he was awarded the Order of Lenin.

Vera Rich

C. W. F. McClare

Colin W. F. McClare, lecturer in biophysics at King's College London, died on 4 January 1977 at the age of 39.

He won an open Exhibition to Emmanuel College Cambridge from Felsted School in 1955 and read Natural Sciences, specialising in chemistry. His interest in applying chemical concepts to biological problems was already apparent in his PhD project on free radicals in biology and was developed further when as a Beit Fellow he studied energy transfer in nucleic acids.

After his appointment at King's College in 1963, he turned his attention to fundamental problems in bioenergetics, especially muscle contraction. He stressed the importance of time scales in thermodynamics and proposed a muscle model employing stimulated resonant energy transfer. He strongly advocated that the secret of ATP lies in the molecular details of its hydrolysis and not simply in its overall free energy change.

Colin was a person of great enthusiasm and intensity of thought. His interests ranged from practical methods of analytical biochemistry to the social and philosophical implications of science. His search for excellence and his competitive spirit showed in his love of discussion and in his sporting activities. As a teacher, he inspired his students through an outstanding ability to make ideas come to life.

He is survived by his wife Gill. His stimulating and ever-helpful presence will be missed by his many friends.

newly on the market

These descriptions are prepared by the staff of *Nature* on the basis of material provided by manufacturers. The Reader Enquiry Coupon faces the inside back cover.

Photoresist illuminators. Oriel. The high efficiency 1,000 W Photoresist illuminators produce highly intense uniform, collimated beams rich in the longwave ultraviolet and shortwave visible, the sensitive wavelength region for most photoresists. The unique optical system provides very high collection efficiency and excellent uniformity with an extremely simple alignment procedure.
Circle No. 42 on Reader Enquiry Coupon

Tube rotator mixer. Gallenkamp. A new tube rotator/mixer suitable for both vertical mixing and horizontal tube rotation, the drum accepts two or four plates of clips. Rotation speed is variable between 6 and 60 rev. min^{-1}, and a clutch on the drive motor allows thed rum to be rotated by hand for easy loading and unloading. A built-in timer enables runs of up to 60 min to be terminated automatically. The overall dimensions are 430×240×340 mm high.
Circle No. 43 on Reader Enquiry Coupon

***p*H meters.** Gallenkamp. Models 7 and 12 have large-scale meter readouts and are intended for routine and research operation respectively. Both read 0–14 (±0.05)*p*H and 1400–0–1400 (±14)mV. In addition, model 12 has an expanded scale which gives a full scale deflection for one *p*H unit at any value within the overall range or 100 mV range. Two additional, logarithmic, scales are provided for ion activity measurements. Models 109 and 113 have digital readouts. The former is a general purpose meter reading 0–14 (±0.01) *p*H and 1900–0–1900 mV. Model 113 also covers the full *p*H range and is accurate to ±0.005 *p*H unit, for research applications. Additionally it reads 1799–0–1799 mV and has an expanded scale facility. For routine laboratory and field studies, a battery-operated *p*H meter (Model 13) is available. This reads 2–12 *p*H with a 2 *p*H overrange at both ends of the scale, and 300–0–300 mV. Models 7, 12 and 113 are suitable for Karl Fischer titrations and all the *p*H meters are supplied complete with combination electrode.

Automatic tissue dehydrator. Reichert-Jung UK. The EM Tissue Dehydrator completely relieves the technician of tissue preparation for electron microscopy. Also, the process is made completely safe—dehydration taking place in a fully enclosed chamber—and highly consistent results are ensured. Specimens are accommodated in up to 51 porous capsules and the dehydration cycle is achieved in 9 automatically controlled stages. Timing of each stage is adjustable to ensure conformity with existing procedures, the tissue being finally taken up to 95% alcohol. There is also provision for immersion in 100% alcohol and propylene oxide, under manual control but still within the enclosed specimen chamber. At each stage, alcohol is added at a predetermined rate, the volume being adjusted to keep overall volume constant throughout the process. The process may be started or stopped at any stage and an alarm, incorporating a variable delay of up to 1 h, indicates cycle completion. On starting, a 50 s delay ensures that the dehydrator is purged of all undesirable vapours before operation.

Reichert-Jung automatic tissue dehydrator.

Fume cupboard. Morgan & Grundy. Traditional fume cupboards contain many joints and corners. To overcome the problems this can cause, Morgan & Grundy have designed a new one piece fume cupboard liner. All corners are welded with a large radius and the base is an integral part of the fume cupboard, so there are no corners or joints. This new design is of stainless steel, making it ideal for radio isotope work. The baffle is also made of stainless steel and is easily removable.

High stability optical benches. Oriel. Many precision optical components mount on to the precision high stability optical benches. These utilise a unique dovetail rail with spring-loaded, wobble-free carriers. Low 'stiction' surfaces allow extremely smooth positioning of the carriers. With care these carriers can be positioned to a precision of 0.001 inch (25 μm) without screw adjustments. Most important, when the carrier locking screw is tightened, the carrier does not shift.
Circle No. 47 on Reader Enquiry Coupon

Automatic blood oxygen dissociation analyser. TCS. The continuous oxygen equilibrium curve of blood can be obtained with the TCS ABOD-analyser in 20 min. Less than one drop of whole blood or haemolysate and 20 min recording times are needed to plot a complete oxygen dissociation curve, and thus obtain the P_{50} value of haemoglobin. The curve is obtained by plotting the absorbance difference of haemoglobin as measured at two different wavelengths against the oxygen partial pressure (P_{O_2}) as measured with a Clark type electrode.
Circle No. 48 on Reader Enquiry Coupon

Precision saw. Anshaw. The Model 7 precision saw from Anshaw Instruments features a choice of two types of quickly interchangeable cutting heads; wire or disk. The wire cutting head was designed to overcome the problem of damage introduced into crystal structures by normal cutting methods. It uses a 0.2 mm diameter, diamond impregnated, continuous wire 'blade' which can be run at speeds up to 10 m s^{-1} and will cut fragile samples, as well as crystals, in practically all materials. The disk cutting head uses standard cutting disks of 100 mm diameter, either diamond or silicon carbide for all precision sawing, including metals, where the extreme sensitivity of the wire saw is not necessary. Various accessories are available, including a precision Goniometer for the orientation and cutting of crystals and also an attachment for automatically cutting circles and cylinders from crystals and hard, brittle materials. The saw has fully controllable cutting speeds and a cross-slide calibrated to 0.1 mm.

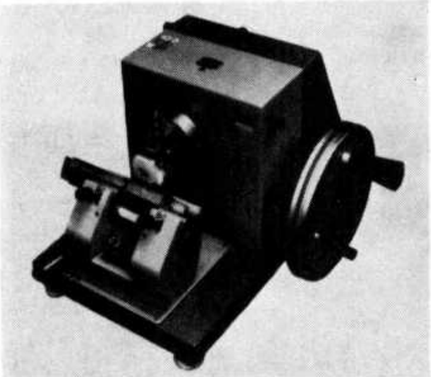
Schoeffel SF 770 and FS 970.

Continuously variable wavelength absorption Monitor/Fluorescence Detector. Schoeffel. By connecting the two units, the SF 770 and FS 970, in series and carefully monitoring the results, confirmation of the spectral characteristics of a compound can be accurately achieved. Determination of the most sensitive method of measurement (absorption or fluorescence) can be made. Extraction of valuable information regarding compounds not clearly separated from each other can be achieved when comparing separate recordings. Both units employ a high energy, low stray light monochromator and offer a selection of light sources (deuterium and tungsten). Both have solid state, miniaturised, modular design.
Circle No. 50 on Reader Enquiry Coupon

Scale culture apparatus. New Brunswick. The MultiGen, an alternative to the spinner flask procedure, is a 1 l or 2 l culture apparatus that can be converted for use with either microbial or suspension cultures. Fully integrated for the control of temperature, agitation, aeration, *p*H and dissolved O_2, the MultiGen also provides facilities for the introduction of sparged air or a gas overlay and includes facilities for heating and cooling, turbine agitation or marine blade stirring. A magnetically coupled drive provides very gentle stirring to vigorous agitation and aeration while an electronic controller ensures reproducible speeds in a range up to 1,000 r.p.m. Precise temperature control from below ambient to 60 °C is achieved by a solid-state thermistor regulator; control accuracy is better than ±0.2 °C. The MultiGen is equipped with its own air supply for aerobic studies. For anaerobic investigations, the pump can be switched off so that CO_2 or other gases may be introduced into the vessel.
Circle No. 51 on Reader Enquiry Coupon

Laboratory sample coater. R. B. Electronics Ltd. A new precious metal coater designed for use in laboratories, the EMS 76 is a compact bench top instrument which diffuses a transparent layer of gold on to non-metallic laboratory samples to enable them to be scanned by an electron microscope. The unit has solid state electronics and incorporates an efficient vacuum gauge which overcomes drift and contamination problems. The 'sputtering' method of coating eliminates the need for rotation or orbital motions. A typical coating time is 2 min for 300–400 Å of gold and the total cycle time is less than 5 min. Virtually any material can be coated, but it is ideal for use on samples of plant or animal tissue, fungus, synthetic fibres and plastics.
Circle No. 52 on Reader Enquiry Coupon

Programmable electronic balance. Sartorius. Model 3802 MP has a weighing range of 6,000 g with 0.1 g readability, operates on the principle of electromagnetic force compensation, and incorporates a microprocessor with a fixed programme to cater for specific problems of weighing. The pan (240× 295 mm) is loaded and the weight read off in less than 2 s. The electronic memory of the balance stores each tare weight automatically after the tare sensor has been touched, while any other required random weights (e.g. standards for check-weighing or batch-weighing) can be similarly stored; only deviations from the standard will then be indicated. The 3802 MP can be used with data processors and control units such as printers, tape punchers, calculators, batch counters, recorders and remote readouts.
Circle No. 53 on Reader Enquiry Coupon



Reichert-Jung disposable knife holder.

Disposable knife holder. Reichert-Jung UK. A new disposable knife holder which fits AO, Reichert, Jung and virtually all other microtomes, overcomes the two most usual objections to the use of disposable blades—the questions of rigidity and adjustment of cutting angle. The holder is of the same size and general cross sectional profile as a standard non-disposable knife, allowing the normal angle adjusters on the microtome to be used. The disposable blade seating and gripping mechanism are so designed that the complete blade/holder assembly is extremely rigid enabling hard specimens to be sectioned without judder.

Pathfinder downflow work station.

Downflow work station. Pathfinder. The new R133/6V range of bench mounted lamina downflow work stations are for use in medical research, diagnostic analysis, haematology and pathological laboratories, and the pharmaceutical, electronics and space industries. The R133/6V features easy operator access and top mounted, high efficiency filters, has air flow or 90 ft min^{-1} (0.45 m s^{-1}) and is fully recirculating with 10% front air make-up. The fully balanced, maintenance free fan system has been specially designed to ensure minimum vibration and a low sound level in the region of 60 dB (A scale) at 1 m. The largest unit in the range measures 1200 mm high by 1924 mm wide by 903 mm deep. The work surface is perforated stainless steel and side screens are of clear Perspex.
Circle No. 55 on Reader Enquiry Coupon

Conductivity meter. Philips. The PW 9505 has a choice of 10 standard measuring ranges, from 0–3 μS cm^{-1} up to 0–100 mS cm^{-1} for which the new Philips plastic conductivity cell PW 9514/60 should be used. By using a specially developed screened cable supplied as standard with the instrument, together with certain Philips glass conductivity cells, the operator can cover the eight middle ranges. A large, easily read scale minimises reading errors, and gives high accuracy with 0.5% class meter. Facilities are provided for conductimetric titrations, reference measurements and ordinary resistance measurements. Reference temperature is normally 20 °C, but it can be extended to 25 °C with a minor modification.

The instrument provides a choice of manual or automatic temperature compensation. The manual mode covers the range from 0 to 50 °C. The automatic mode, carried out with Pt100/1 resistance thermometer or reference cell, covers the range from 0 to 120 °C.

A suitable case for education

We are back in the what's-wrong-with-British-industry business again. After a lull of every bit of twelve months during which there has not been a single weighty document for us to consider in all its worthy detail, the Department of Industry has, with some connivance from the Department of Education and Science, put out a discussion paper, *Industry, education and management* (free from the Department of Industry), which is aimed to "prompt discussion and, more important, action" on the quality of industrial management. The paper fully acknowledges that the poor productivity showing of British industry is by no means exclusively the result of bad management, but tries at least to isolate just a limited number of aspects of the problem—those concerned with technological management by graduates in Britain's manufacturing industries.

If the paper is familiar stuff in many ways, being (so it seems) a distillation of generally expressed views and well-known pieces of information rather than an expression of radically new thoughts, it still serves a useful purpose of confronting the nation yet again with the woeful way in which it doesn't care about engineers and engineering, somehow regarding the creation of wealth as bing a relatively inferior occupation, to be avoided if anything else (preferably involving only paperwork) can be found. The statistics tell the story starkly. As recently as 1969, 40% of graduates entering home employment (excluding the medical sciences) went into manufacturing industries. Now the figure hovers around 25%. At the same time growth in the number of first-degree graduates in science and engineering all but stopped after 1968. Furthermore, tables of after-tax salaries adjusted, as well as can be, for the cost of living in different countries show that top executives on the manufacturing and engineering side are consistently worse paid in the UK than in any other European country. Managerial salaries in industry have lagged very seriously behind inflation and as a result of that and very heavy taxation the salary differential between top executives and average weekly-wage earners is much lower in the UK than anywhere else in Europe save super-egalitarian Sweden.

Nor is there much but gloom in those perceptions of industry which cannot be turned into figures. Television nightly presents the British industrial scene as a battleground between aloof management and irresponsible unions over issues of the most trifling character. Companies are often thought to be run by boards remote from the factory both gographically and in comprehension. Industrial jobs are reckoned to be much more vulnerable than those in the professions, government or academe. Who then is for manufacturing industry; most of all who wants to be on the production side—the Cinderella of the engineering profession?

All of this has, in one form or another, been talked about *ad nauseam* in the past few years without as yet any perceptible improvements, and more doses of it are on the way with a British Association report and then the government's own enquiry into the status of engineers. But in the end it is the educational system which must take up the running, if only because it has a flexibility within it that industry does not have. The first step must be to persuade more intelligent young people at least to sample engineering at school and in university. There seems to be some evidence that young people go into engineering on the basis of the impression that local industry makes on them, either through family connections or simply through exposure to nearby activity. It ought then to be the duty of schools to make sure that local industry really makes itself accessible and explains what it is about to schoolchildren.

Schools cannot expect to do this without one or two of their staff having a more than passing acquaintance with industry themselves. And universities should make sure that engineering is better taught, with richer experience. How many students' summers are wasted by selling ice-cream when they should be learning what industry is about by being in it—and how many universities go to much trouble to persuade industry to find summer jobs for their students? ☐

The world balance: judge with care

Robert Press delivers his verdict on the 1977 Yearbook of the Stockholm International Peace Research Institute.

THE 1977 Yearbook has not avoided the dangers about which SIPRI was warned in *Nature* editorials in 1975 (17 April) and 1976 (8 July). It must be regretted by any objective student in the armament and disarmament community that such an otherwise impressive compilation of military statistics should at times depart from the detachment and neutrality that SIPRI could so usefully provide. Various points are made and opinions or beliefs are expressed which, in the absence of being argued through, have too often an appearance of slanting objective information in a manner which one had hoped an organisation with SIPRI's purpose would avoid.

In analysing the non-nuclear issues, the 1977 Yearbook appears to be very much more concerned with the armaments side of the coin than with the disarmament side. The dimensions of a problem are often stated and supported by a wealth of statistical information but with little or nothing about what is being done to tackle the problem. The Yearbook gives only cursory coverage to the work of the Conference of the Committee on Disarmament (CCD); some analysis of the 1976 sessions would have been useful to the reader rather than merely five brief references to CCD plus lists of working papers tabled in 1976. A SIPRI assessment of the UN Special Session on Disarmament, due to take place in New York in May–June 1978 would also have been welcome. Although this is of great importance as a non-aligned initiative, it is disposed of in a three line reference in an appendix and it is likely to be over by the time the 1978 Yearbook appears.

The Yearbook performs a most useful service in publishing arms trade registers. The section on world military expenditure contains a mass of detailed and interesting data, though lacking in steps to reduce it. One looks in vain, in the index, for a reference to the UN Reduction of Military Budgets (ROMB) exercise, or for the Economic and Social Consequences of the Arms Race (ESCAR). Neither is there reference to a significant US piece of legislation in the International Security Assistance and Arms Export Control Act of June 1976, nor to the UN Secretary-General's study in an 1976 experts' report on the measurement and international reporting of military expenditures. Also lacking is a reference to the Japanese initiative (in the 1976 United Nations General Assembly) with a draft resolution calling for a UN study of international arms transfers. It is significant that this resolution was supported by the West but frustrated by the non-aligned countries, many of whom resent what they considered to be attempts to restrict their capacity to defend themselves.

The most significant point which emerges from a study of the tables on pages 222–3 is the increase in the military expenditure of Third World countries, whose share of global military expenditure appears to have increased from 6% in 1966 to 15% in 1976. One would have welcomed some explanation of this rapid growth. It is not all due to increased arms transfers since these still represent only 14.5% of the Third World's military expenditure. Granted that the arms trade with Third World countries is the area where the greatest increase has occurred, inclusion of trade between industrialised nations would not only have been useful to complete the global picture but would have provided a useful basis for comparison between SIPRI's figures and the United States Arms Control and Disarmament Agency (ACDA) annual volume on world military expenditures and arms transfers.

In discussing developments in nuclear arsenals it is asserted that "the most dangerous development in strategic weapons is the continuous improvement of the accuracy of warhead delivery". One would have welcomed an argued defence for this assertion against the case for greatest accuracy possible for all targets other than cities. In this connection it is arguable (but again not argued) whether, as asserted, military R&D is the "one activity which makes possible the arms race" or whether such R&D is an inevitable consequence of a prior political situation. The latter possibility appears to be recognised in the chapter on international nuclear transactions where it is said that a shift of emphasis "towards the root causes of nuclear proliferation is urgently needed" and that "the best way to slow down nuclear proliferation would be for the nuclear weapon states to show by their actions that they are willing to downgrade the political and military role of nuclear weapons".

The chapter dealing with the 'main events and concerns of the year' (1976) inevitably refers to "the new surge of concern about the possible proliferation of nuclear weapons to countries which do not already have these weapons" and it looks upon the year as a "a particularly meagre year for efforts to slow down the Soviet–US arms race to limit armaments". Even the Peaceful Nuclear Explosions Treaty, signed in 1976, would in SIPRI's view, like the 1974 Threshold Test Ban Treaty, be better to remain unratified since it may only delay a comprehensive test ban. One can readily agree that any treaty which allows PNE to continue cannot be truly described as a comprehensive test ban treaty.

Given the importance of the whole issue of nuclear weapon proliferation, the confusion and emotion that arises in discussing the inter-relationship of civil nuclear capability and the potential diversion to military application, the Yearbook's treatment of the proliferation issue is at times less precise and objective than one could hope for from SIPRI. For example, in a reference to the proliferation of uranium enrichment technology to non-nuclear weapon countries,

Keystone

Launching the Cruise Missile

“in particular to FR Germany, the Netherlands and South Africa”, the Yearbook fails to point out that these three countries were themselves simultaneously developing isotope separation technology. This may be “proliferation” in one sense but not in the generally accepted sense of commercial transfer of know-how and equipment from nuclear haves to have-nots.

It is claimed that while the Soviet Union followed the USA, UK and Canada in negotiating bilateral agreements, they did so in “a more cautious manner”, following their dispute with China, and they have been “rather restricted in their nuclear transactions . . . whereas some Western European countries have adopted more aggressive commercial practices”. Yet in the same chapter it is noted that when Canada permanently cut off its nuclear sales to India, two years after the Indian nuclear explosion (1974), “the Soviet Union agreed to sell 200 tons of heavy water to India instead”. There is no mention that this action was taken before a safeguards agreement with IAEA had been negotiated. The Yearbook has no hesitation in pointing to a USA offer “to sell nuclear reactors to Israel and Egypt even though these States are not subject to NPT Safeguards” without adding, for the readers’ information, anything about the offer being subject to IAEA or US safeguards. Reference to the major nuclear suppliers’ efforts to minimise the risk of diversion of nuclear equipment and material is accompanied by the comment “which they are so eager to supply”, without any acknowledgement of those countries’ obligations under the NPT.

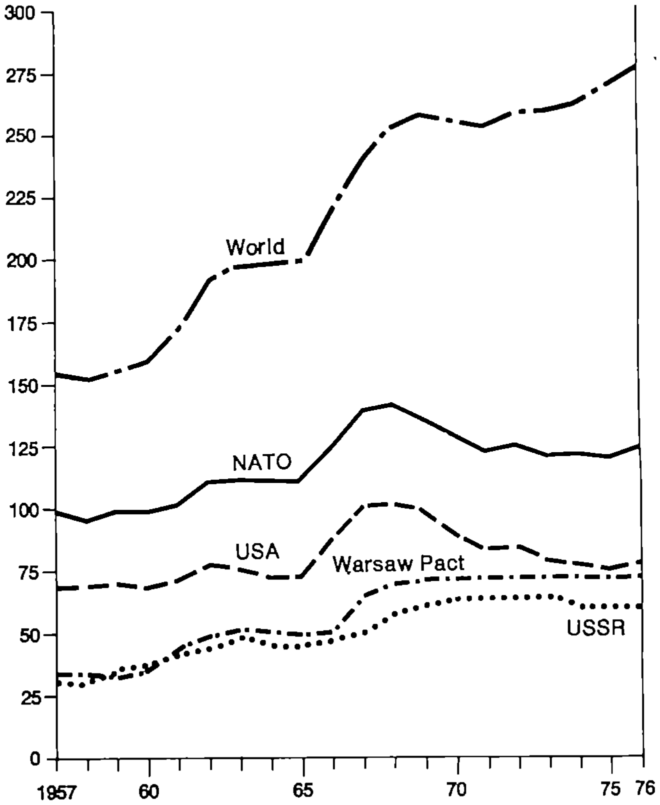
Incidentally, under a sub-heading of nuclear explosives as by-products of a peaceful nuclear power programme, in Fig. 1.1, one wonders about the value of the statement: “The marginal cost of so producing a nuclear explosive device may be no more than a few hundred thousand dollars”. The reader may well wonder whether this is an informed estimate and what is meant by “marginal cost”; if not an informed estimate, does the statement render any positive service to the cause of non-proliferation? However, in this context, a more realistic note is struck when it is observed that “a lack of access to a commercial reprocessing plant would not necessarily prevent the proliferation of nuclear weapons to countries which take the decision to acquire them directly”.

On ‘the plutonium problem’, the Yearbook falls into the usual trap of failing to separate the ‘nth country’ problem from the potential ‘terrorist’ problem and therefore fails to distinguish between the different kinds of risks arising and then of course in the different kinds of safeguards to be adopted. In a reference to breeder reactors it cites the usual “dangers” arising from their preferred fuel being “plutonium of weapons grade” while appearing to underplay the contribution that any grade of plutonium can make for the same purposes or the relative attractiveness of enriched uranium for bomb making. In general, one would have preferred SIPRI to examine various aspects of the plutonium and breeder issues in a perspective which would inform and admit a reader’s own judgment to be made rather than appearing to lean towards an anti-breeder if not an anti-nuclear viewpoint. For example, does SIPRI have a view on whether proliferation stemming from breeders can be forestalled by proper design, both technical and institutional; if it can, should proliferation-resistant breeder systems be set aside in face of forecast world energy requirements and particularly in face of the forecast ‘CO_2 problem’ arising from the burning of fossil fuels?

From the point of view of avoiding unnecessary alarm, or providing the neutral reader with a clear perspective, the section on ‘Accidents of nuclear weapon systems’ is one of the most unsatisfactory in the Yearbook. Whether the picture is presented as “substantially more serious accidents involving US nuclear weapons than the public were aware of” or “about one every two and a half months”, the text on these is too often laced with such expressions as “it is reasonable to assume . . .”; “it is not unlikely”; “there is thus even some possibility . . .”. These are the phrases which may leave some readers with an impression of frequent nuclear accidents when only a related weapons ‘system’ or vehicle may have been involved in either a major or minor accident, or even only an incident of some kind, and where “there is no record of any of them having involved nuclear weapons in transport” or where “there is no indication of whether or not any of these accidents involved nuclear weapons”.

World military expenditure, 1957-76

US $ thousand million, (1973 prices and 1973 exchange rates)



Source: SIPRI data

The text specifically states that “there is still no direct evidence of involvement of nuclear weapons in the case of the French and British weapons systems”, yet the same chapter contains a table under the heading of “British nuclear weapon incidents”. Admittedly this particular inclusion is explained away in a series of footnotes but, even within SIPRI’s own justification for such presentation, would it not have been more helpful and reassuring to the reader to make the point that in the West there is no chance of a nuclear accident, involving even the slightest escape of radioactivity, being concealed, and that on this basis the record is one pointing to the very high standards of safety employed? In any event, in the light of the evidence presented, it is difficult to accept what the conclusions offer as being “clear” or “incontestable fact”.

These various observations in respect of SIPRI’s presentation of both non-nuclear and nuclear issues are made to illustrate the need for careful examination of various assumptions made in SIPRI’s analysis before accepting the general conclusions drawn. At the same time they illustrate once again the dangers about which *Nature* editorials have warned in previous years and, hopefully, will encourage SIPRI to avoid a continuing trend that could so easily destroy the value of a reliable and objective reference work for which the need is great. □

Man-made process

Chris Sherwell reports on a study of man's involvement in the spreading desert

HOWEVER discomforting it is for Western man to learn that he wastefully squanders his resources, his lesson is not nearly as painful as the one being learned by his contemporary living in the arid zones of the underdeveloped world. For there, that most precious and finite of resources, the land itself, is actually being lost, and at an alarming rate.

Some wealthy countries experience the same problem. Fifty million of the 163 million acres managed by the United States Bureau of Land Management, for example, are in 'poor' or 'bad' condition. But the US has the wherewithal to combat the phenomenon: the causes of desertification are understood imperfectly, but well enough for something to be done.

The real problem is conjuring out of nothing the political will to implement a comprehensive plan that deals with the poor countries' marginal lands. It is a problem which will confront the massive UN Conference on Desertification starting at the end of this month in Nairobi, when just such a plan will be drawn up. As with past jamborees of this sort—on Water earlier this year, Human Settlements last year or the Environment in 1972—a flood of papers is besieging the conference. One of the more important was published last weekend by the Washington-based Worldwatch Institute*.

Entitled *Spreading Deserts—The Hand of Man*, it is, as its title suggests, unequivocal about causes and solutions. It calls desertification an ecological phenomenon but says it is a human problem. "People cause it, people suffer its consequences, and only people can reverse it." Governments may find it difficult to devote substantial resources to combating a "seemingly long term and nearly invisible problem like ecological deterioration", but the consequences of desertification—undernutrition and famine, unemployment and migration, deepening poverty and human desperation—are "neither distant nor invisible".

Some of the statistics cited in the study confirm the need for action. About 14% of the world's population —630 million people—live on arid or semi-arid lands. Of this number, some 12% live on lands already almost useless and face the loss of their livelihood.

The decline in the quality of the land has meant a decline in the quality of people's diet, chronic ill-health, swollen ranks of urban migrants and lost economic potential. Indeed, cumulative degradation of rangelands and nonirrigated farmlands in the arid zones has, according to the study, held their combined annual productivity "more than $12 billion below its potential level"; of sixteen underdeveloped countries in the arid areas, for example, only two significantly increased their per capita grain output between 1950 and 1975.

This decline is more popularly portrayed in another way. Along the southern fringe of the Sahara alone, 650,000 km^2 of land once suitable for agriculture and grazing has been lost in the past 50 years. Some 100,000 ha of range and cropland are lost to desert each year along the Sahara's northern margins. Elsewhere—in the Middle East and in Western Asia—the process's hold is "particularly long-lived and advanced". It is also taking place, as the accompanying map shows, in many of the western hemisphere's drier regions.

However, although natural desert encroachment is a real enough threat in some areas, the process of desertification is more correctly one where human action causes the desert to spread. A product of land-use patterns as well as climatic fluctuations, desertification will occur where land is abused in arid and semi-arid zones regardless of the actual proximity of the climatically-created deserts. The effects of severe and prolonged land abuse are, of course, intensified by extended droughts. But to review the current theories and knowledge on world climate, says the study, is not only to "sense the urgent need for research efforts" on climatic trends; it is also to "see without question that people and their livestock are helping to downgrade the carrying capacity of arid lands and to create new spots of desert".

Desertification is not new; what makes today's problem especially acute, says the study, is the scale of suffering when the rains fail, and the scale of destructive human pressures. Rudimentary modern medicine has helped produce the 3%-a-year increase in population prevailing in the areas, which means more people are reliant upon the pastures and croplands there. At the same time the modern political and social order has grown inimical to the existence of the desert dweller, restricting nomadic groups who are well-adjusted to a harsh environment and encouraging sedentary agriculture.

The results are all too obvious. More people with more herds cultivate more areas to feed more mouths. Soils deteriorate, yields decline, pastures disappear, grazing land grows more distant and land around more intensively used water holes perishes. People become a threat to themselves: what they do to ensure individual survival in the short term is detrimental to the society's long term survival. As the Worldwatch study sees it, social systems and ecosystems are on a collision course; populations in the arid areas have reached the ecological danger point.

The study is also clear about what needs to be done. For a start, herd

sizes should be reduced. Livestock should be valued for its quality rather than its abundance. If animal numbers in the Sahel were maintained at half the 1971 level, with modern management techniques the region's output of meat and milk could be double that level. Farming in the sedentary zones should also be improved, to halt its spread onto pasturelands. Farmers need knowledge and equipment to grow sufficient food using the best lands without loss of fertility; back-up for subsistence farmers has hitherto been neglected in favour of cash crops, which have themselves exacerbated the lot of the rural poor.

In addition, couples must perceive the advantages of small families. Population growth, says the study, prohibits a return to the ecologically sustainable rotation systems, so new cropping systems, along with tree-planting programmes, are the only alternative. Also, to urge the resettling of nomads and the killing of goats is to oversimplify: a modernised version of the nomadic way of life may be necessary, with clan leaders, aided by specialised advice, regulating grazing and migration through large herding cooperatives.

A major goal of arid lands development, says the study, must be to prepare peoples and economies to live through the inevitable droughts without trauma. Protection against famine, it says, is not a simple technological problem. Its success depends on nothing less than "the broad shape of national development and the character of the prevailing socio-economic institutions".

Plainly the challenge is great. It is a challenge facing the UN Conference. If that fails, and past experience does not augur well, the people most affected will be left to face it alone. They have done so before. But their chances of successfully continuing to do so are not improving. ☐

ICARDA gets down to business

THE International Centre for Agricultural Research in the Dry Areas (ICARDA), having shaken off its troubled origins, is poised to embark on an ambitious research programme under the guiding hand of Dr Harry S. Darling, now president of Wye College, who is preparing to move to Beirut as ICARDA's director general.

The most recent of the international agricultural research centres, ICARDA will focus on improving food production in areas with an annual precipitation of 300–800mm that is concentrated largely in the winter months. Its findings will affect a region extending from Morocco to Pakistan with crops covering some 70 million hectares in 20 countries.

ICARDA staff members like to say that the centre "was born running", because it absorbed some of the facilities and personnel of the Arid Lands Agricultural Development (ALAD) programme of the Ford Foundation. But it was soon faced with obstacles that brought it almost to a complete halt. After the decision to establish head offices in Beirut in Spring 1974, war broke out, and most of the staff scattered to Cairo, Aleppo and Damascus. Negotiations with Syria and Iran to obtain land for research stations were conducted chiefly by Canada's International Development Research Centre (IDRC), which had been appointed the executing agency for ICARDA; formal agreements were signed with Syria in June and with Iran in July last year. IDRC also reached an agreement with the Ford Foundation to insure that ALAD activities relevant to ICARDA's mandate, notably the collection, testing and exchange of plant genetic materials, were continued.

On top of its research on the region's crops, ICARDA has been designated as the world international centre for barley, lentils, and broad beans. Barley, one of the world's oldest crops, is particularly important in the region. But wheat is usually preferred because it has a higher gluten content and makes a more cohesive loaf of bread. Barley's two major advantages over wheat, however, should encourage its utilisation as human as well as animal food. One of these is that in regions with less than 500mm of annual rainfall it can outperform wheat; where rainfall is 375 mm or less, it is practically the only cultivable cereal. The other advantage, hinted at by current research, is that barley is susceptible to improvement, notably by an increase in content of lysine, an essential amino acid that is absent or exists only in minimal amounts in most food grains.

At present, barley yields in the Middle East are very low, and four ALAD-ICARDA barley varieties introduced in nurseries in 1976 indicate that performances can be considerably improved. Research is under way to deal with problems of disease susceptibility, lack of winter hardiness, intolerance to high temperatures, and insects. These trials will be undertaken in the ICARDA stations near Aleppo and Tabriz.

The food-legume crops improvement programme also continued in 1976. It consisted mainly in breeding and distributing germ plasma of three major pulses: lentils, broad beans and chickpeas. The major emphasis is on the development of high-yield, stable varieties, and of lines suited to mechanised harvesting. There is a forage-crop improvement programme, and some of the ALAD research work in wheat, maize and grain sorghum is being continued; so is the evaluation of several hundred lines of triticale, a man-made hybrid of wheat and rye.

Next year, ICARDA is expected to expand its activities. These will include the study of environmental systems throughout the region, the establishment of principles on which to base the development of appropriate farming strategies, and research into socio-economic constraints that limit the actual and potential production of existing farming systems. Finally, a training programme to help apply research findings is being set up.

From its inception until the end of last year, ICARDA's total budget barely exceeded $3 million. But now that 'running speed' is being resumed and total staffing has exceeded 50, more funds are required for operations and capital development. Interest in the programme is illustrated by the commitment for 1977 of a total of $4 million, the major contributors being the USA with $1 million, the IDRC and Canada with $600,000, Iran and Saudi Arabia with $500,000 each, and the World Bank and Australia with $220,000 each. Estimated expenditures of $4.85 million for 1978 and $7.77 million for 1979 have been submitted to the Board of Trustees, which is made up of representatives of some of the region's governments, agricultural research centres and donor agencies.

Alexander Dorozynski

Pieces of action

Sandy Grimwade reports from Washington on some of the non-legislative developments concerning recombinant DNA research

ALTHOUGH much of the attention of the followers of the recombinant DNA debate has focused on the progress of the controlling legislation at present under consideration in Congress, activity in research labs and on campuses has not been completely stilled. A major supplier of laboratory chemicals has taken some unprecedented steps to control the use of its restriction enzymes—the enzymes which are used in the preparation of recombinant DNA molecules. A Maryland lawyer has sued the National Institutes of Health (NIH) on behalf of his son to postpone recombinant DNA experiments which he claims are at present illegal. And another group of scientists has petitioned Congress over the proposed legislation.

The firm which has taken a step practically guaranteed to lose it customers while bringing praise from those who favour a cautious approach to recombinant DNA research is Miles Laboratories Inc. Miles has been an important supplier of restriction enzymes for several years, and last year sponsored a symposium on recombinant DNA research. In themselves restriction enzymes can cause no hazard; a competent molecular biologist, moreover, would be able to prepare a private supply with a week or so of work. Miles now requires its customers to appoint a control officer who will be responsible for ensuring that its reagents are used in accordance with the NIH guidelines, and who must sign all orders for such reagents.

A spokesman for Miles said that the firm had taken this step on both moral and legal grounds, and that the restriction will be kept in force until the federal legislation now pending becomes law. Miles is applying this condition to all sales of restriction enzymes on the advice of its lawyers so that the entire burden of responsibility for their use is shifted to the customers. The spokesman admitted that the reaction from scientists to this additional bureaucratic requirement had not been entirely favourable. Its action is unilateral; other companies in the business are apparently not planning to follow suit.

The action of the attorney in Frederick, Maryland, who filed suit under the National Environmental Protection Act on behalf of his 2-year-old son against NIH, was aimed at halting experiments planned to take place at Fort Detrick before publication of an Environmental Impact Statement (EIS). The experiments, which would involve the splicing of segments of the mouse polyoma virus genome as well as the whole genome into plasmids and cloning in *E. coli*, would under the NIH guidelines require the highest level of physical containment, the P4 level. The objective of the experiments is to discover whether the cloned gene segments of the polyoma virus, which causes cancer in mice but has no effect in humans, are expressed in *E. coli* and whether the gene products can raise antibodies in mice treated with the *E. coli* clones.

NIH have agreed to produce an EIS in 30 days, although it is not clear at this point whether the statement will address the potential impact of this particular experiment or recombinant DNA experimentation as a whole. The attorney, Ferdinand Mack, sees the NIH action as a concession that they were ignoring the law requiring the publication of an EIS. In fact the EIS from NIH on the complete recombinant DNA guidelines has been hanging fire for over a year now, a point which does not follow the letter of the National Environment Protection Act. Friends of the Earth have filed a separate injunction enjoining a halt to all federally funded research in this area until the EIS is published.

The latest petition from scientists follows the statement about a month ago from the Gordon Conference on Nucleic Acids urging Congress to drop or tone down the proposed legislation. Signed by 140 scientists attending the Conference on Biological Regulatory Mechanisms—85% of those attending—the new statement was sent to members of Congress as part of a late-starting but vigorous effort by the proponents of recombinant DNA research to urge more lenient legislation. ☐

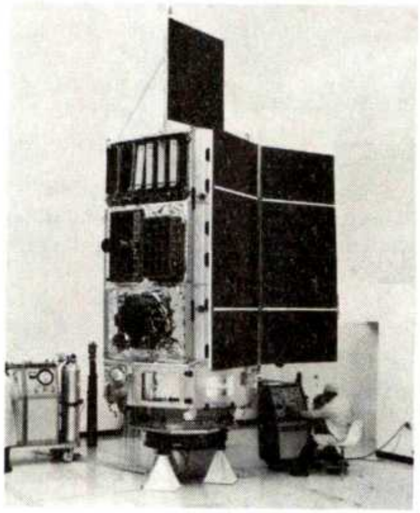
Scanning the universe

X-RAY astronomers are not having much luck at the moment. ESA's decision to schedule Exosat on the Ariane launcher upset the European space community, less because of Ariane's unknown reliability than because of the spectre of budget cuts for other projects and an almost certain delayed start to the mission. Though US astronomers have fared no better in recent months, some improvement may now come with the first satellite of the HEAO mission, which NASA expects to launch this week.

The High Energy Astronomy Observatory (HEAO) project was initiated in 1968. Budget cuts have since halved its size, but still the three-satellite mission involves the heaviest Earth-orbiting satellites ever launched. NASA had hoped to launch the first satellite, HEAO-A, on 15 April, but problems with the spacecraft's gyroscopes caused cancellation at the last moment; re-design and qualification of the gyros have now been completed. Though a launch scheduled for 30 June was missed, lift-off is fixed for the early morning of 12 August.

The HEAO observatories are designed as sensitive high-resolution detectors of X-rays and γ-rays. Building on the success and experience of such missions as Uhuru, Copernicus, Ariel V and SAS–3, HEAO could help resolve controversies over the existence of black holes and the nature of quasars, pulsars and X-ray bursters. No one commits $237 million solely to fashion, however, and the HEAO mission has a solid, professional set of scientific objectives to pursue.

HEAO-A is an all-sky X-ray survey mission. A circular, 445-km high orbit will place it above the absorbing atmosphere and below the damaging radiation belts. During its six-month lifetime it will scan the complete sky and systematically map both discrete X-ray sources and diffuse X-ray emission and absorption. The four experiments on-board provide high resolution (up to 5 arc-seconds) for position and size determinations and good time resolution for investigating the complex behaviour of variable sources. Crude spectral data will also be obtained.



TRW

HEAO-B is due for launch in 1978. Containing a wide-aperture imaging X-ray telescope with a sensitivity 10,000 times greater than any previously flown, it will latch on to specific sources of interest pinned down by HEAO-A and study them in great detail. The mission lifetime is estimated as one year. HEAO-C, another all-sky survey satellite and due for launch in 1979, will systematically scan for cosmic and γ-ray sources.

Stuart Sharrock

USSR

Well provisioned

The Soviet Union is at present going through the rituals of adopting a new constitution. Vera Rich reports

THE DRAFT of the constitution which has been presented to the public and is now the subject of 'discussion' (in effect, eulogy and explanation) in the media is, from a political point of view (State structure, the rights and duties of citizens and so on), little different from the existing version. But there is one interesting feature: the emphasis placed on the State's involvement in Science.

The existing constitution, promulgated in 1936, makes virtually no mention of science. In contrast, the new draft stresses that "in accordance with the requirements of society, the State guarantees the planned development of science and the training of scientific personnel", and the implementation of the results of scientific research in the economy (Art. 26).

A new clause (Art. 48) guarantees "freedom of scientific, technical, and artistic creativity", which is "ensured by the wide development of scientific research, inventive and rationalising activity and the development of art". The same clause pledges state support to "voluntary societies and creative unions", and guarantees the rights of authors and inventors. The "right to work" is now extended (Art. 40) to include the right to choose a profession "in accordance with vocation, capabilities, professional training, education, and in accordance with State needs".

A somewhat ambiguous reference to science in the 1936 version has now been clarified: instead of guaranteeing the right of asylum to foreign citizens persecuted for "defending the interests of the working people, or for scientific activities", which suggested that the Soviet Union hoped to play host to latterday Galileos, the reference is now to "progressive social, political, scientific, or some other creative activity".

The new references to science clearly indicate a serious government commitment. To stress their importance, *Pravda* recently published a long statement by scientists of the Siberian Branch of the Soviet Academy of Sciences, a body which, being less than 20 years old, can well serve to express the viewpoint of the modern scientific community. In effect, the statement proved to be little more than a eulogy of the Soviet system of "guaranteed employment".

Not surprisingly, the eulogies are not echoed by dissident and refusnik opinion. Dr Veniamin Fain, a physicist who was allowed to emigrate in June, recently told *Nature* that he was very doubtful that the new clauses would bring about any major changes as regards academic freedom, and the status of refusnik scientists.

The picture he describes, of scientists dismissed from their posts and forced to find work as janitors or lift-attendants simply because they wish to leave the country, accords ill with the new pledge of choice of profession in accordance with one's education. And the history of the Voronel-Azbel seminar hardly reflects the "support" pledged to "voluntary [scientific] societies". Nevertheless, a right once granted on paper can form an important rallying point for those who wish to press for its implementation. □

EEC

Halocarbon decision

The European Commission has taken a first cautious and hesitant step towards restricting the use of halocarbons in EEC countries. A special correspondent reports

THOUGH not convinced that halocarbons are harmful, the European Commission is sufficiently impressed with the evidence so far, particularly from the USA, that it has decided to ask environment ministers in the Nine to ban any increase in manufacturing capacity for the halocarbons F-11 and F-12. The Commission also wants immediate measures to "encourage" industry to avoid any leaks of these gases, and to "encourage" industry to intensify research into possible substitutes and alternative methods. And it believes research into the effect of the gas on the environment should be stepped up, with more cooperation and coordination between researchers in the member states.

The Commission has been holding meetings with national experts since January. If all goes according to plan, the EEC's Economic and Social Committee and the European Parliament will give their views on the Commission's proposals in September and October, and the environment ministers will make their decision in November. The Commission will then in the second half of next year assess the effects of halocarbons on man and the environment and draw up an EEC policy on the subject. Such a policy would need the approval of the ministers of the member countries.

In the meantime the Commission will see if it should try to co-ordinate the work, or if perhaps it should give limited aid under its programme of indirect action. European research at present is concentrated on measuring, on Earth and *in situ*, concentrations of the minor constituents of the atmosphere, studies of spectral properties and reaction speeds and development of mathematical models. □

ARGENTINA

Scientist's plight

ELENA H. SEVILLA is the latest Argentinian scientist whose plight has come to public attention. Senora Sevilla is a 29-year-old atomic physicist who had been teaching at the University of the South in Bariloche and doing research at the Balseiro Institute.

She was arrested in November 1975, just five days after having had a Caesarian operation and whilst still in hospital. Her husband had been arrested two months earlier. Lack of evidence against her led to her acquittal in a court in Rawson in January 1976, but since then she has been held in preventive detention "at the disposal of the executive power". She has been moved several times from prison to prison, most recently to the Villa Devoto in Buenos Aires. There she shares a cell with 20 other women in conditions which are by no means good. Diet causes great concern, and prisoners, whilst allowed to receive three books each month, may not have university textbooks or books related to economics, history, chemistry, physics or languages.

In December 1976, Senora Sevilla applied for permission to leave the country under Article 23 of the Constitution, which allows for those held in preventive detention without charge or trial to opt for exile if they so wish. She has never received a reply. According to Amnesty International, Elena Sevilla has never been politically active. Amnesty asks fellow scientists to write on her behalf to the President, General Jorge Rafael Videla, Casa Rosada, Buenos Aires, with a copy to the local Argentinian Embassy.

correspondence

MLS international standard

Sir,—It is with regret that I report an error in the article 'Astronomy's own cloud' (9 June, page 478). The Australian system, 'Interscan', one of several Microwave Landing System (MLS) proposals, has not been adopted as the next international standard, and has not (yet) beaten all comers. The matter is, sadly, complicated if not bedevilled by partisan politics and if you were to read certain American reports, for example *Microwave Systems News* (June 1977, page 33) you would learn: "US Landing System going world wide".

The pedantic, boring truth is that the All Weather Operations Panel of the International Civil Aviation Organisation (ICAO) met in Montreal last March to consider the various MLS proposals. They recommended by a narrow majority vote (6–4), that the 'scanning-beam' (US–Australian) MLS scheme be submitted to the ICAO Air Navigation Commission for consideration for adoption as the international standard at an ICAO meeting to be called later this or early next year. Recommendation for adoption—no more, no less.

It is not altogether clear from the generally accessible published material just what the differences between the American system and the Australian 'Interscan' are. We can certainly say that the Australian idea was taken over by the Americans, whose own originally proposed schemes were demonstrated to be less than competitive. In this sense the Australians do indeed have cause for pride.

One must not forget that the Germans and the English both have advanced MLS proposals, and that the selection at Montreal of the US–Australian scheme was perhaps helped more by procedural niceties than by an honourable and convincing demonstration of the inferiority of the European work (*Aviation Week and Space Technology*, 28 March, page 26 et seq., *Frankfurter Allgemeine Zeitung*, 14 April, page 8). This was the subject of objections at the time and the reason for protest abstentions in various votes during the meeting.

One cannot altogether blame the Australians for blowing their own trumpet since they have suffered sorely in publicity at the expense of the Americans—their trumpet should nevertheless play the written notes and not extemporise.

It is to be expected that the European interests in MLS will pursue vigorously a re-appraisal of the Montreal deliberations, with a view to demonstrating the technical superiority of one of the systems over the others —a demonstration which has not yet been attempted.

Yours faithfully,

David Ll. Hills
Max-Planck-Institut für
Radioastronomie, Bonn

Wind power for the UK

Sir,—Dr Clement states that my estimates of wind-power are "grossly exaggerated" and that the environmental impact would be unacceptable. He compares my results with those of the recent Department of Energy report *The prospects for the generation of electricity from wind-energy in the United Kingdom* which considers the installation of windmills on hill-top sites (many of which would undoubtedly be environmentally unacceptable besides involving greater construction and transmission costs) and within a 15 km coastal belt. The total area involved in deriving their "upper limit on energy" is confined to about 1% of the UK land area. The more dispersed system which I discussed covers—as Dr Clement correctly computes—some 5×10^4 km^2 of land area, reduces the transmission costs per kW, and provides 20 times the energy.

The impact of wind generators on other land uses such as agriculture is minimal, and the visual impact must be judged in relation to that associated with any other scheme capable of providing comparable useful energy. If, for example, it were proposed to provide the UK energy gap predicted by the end of the century by the construction of new nuclear capacity on coastal sites, much of the south and east coasts of the country would require an average density of nuclear stations corresponding to about 0.2 GW km^{-1} of coastline. If, as in my wind example, environmental and other objections permit only about one-third of the coastline to be so used, these areas will require about one 275 kV twin-wire transmission line running inland for every 2 km of coastline. At 4 towers per km the density of pylons (whose construction is very similar to that of the windmills I considered) is then about twice that of the windmills. The nuclear stations themselves would of course involve both visual and other environmental problems as well.

Dr Clement seems to prefer to ignore the energy problems which we, and other countries, now face; perhaps he believes—as the Secretary of State has recently stated—that 13 GW of additional nuclear capacity (half in FBRs) would be more than adequate to meet our energy needs "in the foreseeable future" (*Guardian*, 3 June). Although this capacity would replace the oil-fired generating stations now in use (11 GW), it could make little contribution to the much larger energy demand at present provided by oil and gas for transport, industry and the heating of buildings. Owing to the large fluctuations in the latter, an installed capacity of 200–250 GW would be needed by the end of the century.

A nuclear capacity of 13 GW may indeed represent what it is feasible to build on this time scale, and if so it is clearly essential both to introduce every possible economy measure now and to proceed as fast as possible with the development and installation of alternative sources capable of making a more significant contribution. Wind-power is the most highly developed, has a large potential and is the cheapest, although wave, new forms of tidal and direct solar energy may also be important.

In comparing the cost of wind energy with that derived from nuclear and fossil fuel stations the Department of Energy report has considered only the replacement of base-load electricity, rather than the much more important energy gap discussed above. Owing to the large fluctuations in this energy demand, it is not permissible, as the report has done, to include the interest on capital for wind generators but exclude it for conventional systems, and the high costs they derive for wind-power are not relevant; the actual costs, both capital and running, for producing a given useful energy from wind are about one-third those of a nuclear system.

Yours faithfully,

Enzymoimmunoassay: techniques and uses

from J. Landon

IMMUNOASSAYS are being used increasingly in clinical practice to detect and measure antigen concentrations in biological fluids Some procedures do not employ a labelled reactant, including radial immunodiffusion, rocket immunoelectrophoresis and various automated systems. They are, however, applicable only to proteins, and although simple and precise have limited sensitivity and need high concentrations of monospecific antisera. In 1960 Yalow and Berson introduced a radioimmunoassay (RIA), to determine circulating insulin levels, using ^{131}I-labelled insulin and appropriate antiserum. Use of a radioisotope for labelling a reactant overcame the need for monospecific antisera, improved sensitivity markedly and enabled haptens as well as proteins to be assayed.

Many other possible labels have been studied in recent years, including enzymes, fluorescent or chemiluminescent molecules, viruses, proteins, particles and free radicals. Enzyme labelling has been the subject of most work and provides a feasible alternative to radioimmunoassay. Various names are current, including enzymoimmunoassay (EIA), enzyme-linked immunoassay and enzyme-linked immunosorbent assay (ELISA). The term EIA is preferred because of its similarity to the term radioimmunoassay and because it prevents confusion with the measurement of enzymes by radioimmunoassay.

Advantages and disadvantages

Reasons for the emphasis given to enzyme labelling include its previous applications in histochemistry and cytochemistry; the availability and relative cheapness of many enzymes and of manual and automated systems for their assay; the long shelf life of the labelled product (which can be measured in years); lack of hazards during labelling; and a sensitivity, specificity and applicability similar to radioimmunoassay. Nonetheless, the additional step of determining enzyme activity prolongs the assay and increases imprecision, while the amplification made possible by the use of an enzyme to attain sensitivity will also magnify any error. Furthermore, biological samples may themselves contain enzymes with similar biological effects which can cause a high and variable background, and other factors such as haemolysis may affect the result.

The ultimate success of EIA will depend on its merits as compared with the widely used radioimmunoassay. The relative merits of radioisotopes and of enzymes for labelling has recently been surveyed by Ekins (*Lancet* **ii** 176; 1976). Briefly, RIA is relatively inexpensive, very sensitive and precise, and the sample provides no background signal. But isotopically-labelled reactants have some disadvantages including a slight health hazard associated with their production, and a limited shelf life. Short shelf life poses considerable commercial problems since it necessitates frequent radioiodination and increases costs of production, quality control and distribution.

Analytical techniques

Various procedures using enzyme-labelled antigen or antibody to assay antigens have been developed. The reactant is labelled with one of a wide variety of suitable enzymes (acetylcholinesterase, alkaline phosphatase, malate dehydrogenase, peroxidase and β-galactosidase, for example) (see Sharpé *et al. Clin. Chem.* **22**, 733, 1976; Wisdom *Clin. Chem* **22**, 1243; 1976). At the end of the assay the enzyme-labelled reactant is easily measured by reaction with substrate.

Techniques using labelled antigens

One approach involves a separation step and is similar to RIA; enzyme-labelled antigen and the sample are incubated with a limited amount of specific antibody and the proportion of label distributed between antibody-bound and free fractions gives, by comparison with a set of standards, the concentration of antigen in the initial sample. Antibody-bound and free fractions may be separated by adding a second antibody, or by the use of solid-phase systems in which the first antibody is linked to an insoluble matrix. A combination of these two methods, in which the second antibody is covalently coupled to cellulose—the double antibody solid phase system (DASP)—has been successful.

The separation step in an EIA can serve a second important function, namely to separate the exogenous enzyme being used as the label from any endogenous enzymes in the sample with similar biological effects or from any other constituents in the sample, such as enzyme inhibitors, which could influence the signal.

The first EIA was developed for immunoglobulin E by Engvall and her colleagues (*Immunochemistry* **8**, 871; 1971) and assays have now been described for a wide range of antigens including albumin, carcinoembryonic antigen, human placental lactogen, insulin, cortisol, total oestrogens and testosterone.

The separation step can be avoided in some EIA. In one category, which can be termed 'quenching' assays, there is steric hindrance by the antibody in the bound fraction of the reaction between the substrate and active site of the enzyme (Rubenstein *et al. Biochem. biophys. Res. Commun.* **47**, 873; 1976). Thus only the free fraction retains enzyme activity. Use of enzymes such as malate dehydrogenase and glucose-6-phosphate dehydrogenase that require cofactors, obviously enhances the potential for steric hindrance. Assays of this type have been developed for various haptens, including several drugs of abuse, anti-epileptic drugs and digoxin and have been applied to urine, saliva and plasma.

Alternatively, assays exist of the

J. Landon is Professor in the Department of Chemical Pathology, St Bartholomew's Hospital, London.

'enhancement' type in which antibody binding potentiates enzyme activity. Such an assay has been described for thyroxine using a thyroxine derivative covalently linked to malate dehydrogenase such that the enzyme has little activity. Enzyme activity increases markedly after adding anti-thyroxine antibodies (Ullman *et al. Clin Chem.* **21,** 1011; 1975). This assay has also been incorporated onto a multichannel biochemical profiling instrument (Galen & Forman *Clin. Chem.* **23,** 119; 1977).

The time saved and the precision gained by avoiding separation compensates for the enzyme detection step and such assays are being increasingly used. This approach is, however, probably not applicable directly to the assay of proteins, and problems due to comparable enzymes and other constituents in the sample may limit the sensitivity that can be achieved.

Techniques using labelled antibody
The standard approach is to react the target antigen with excess labelled specific antibody and to remove unreacted labelled antibody by excess antigen covalently linked to a solid phase so that the enzyme activity associated with the antigen in solution is directly related to the antigen concentration (Maiolini *et al. J. Immun. Methods* **6,** 355; 1975; Barbour *J. Immun. Methods* **11,** 15; 1976).

Sandwich technique: this approach was first introduced by Wide in 1971, using radioisotopic labelling, and is applicable to the assay of large molecules with more than one antigenic determinant. It is designed to improve specificity by excluding fragments of the molecule from influencing the results. Excess antibody covalently linked to a solid phase and directed against one end of the antigen is incubated with the sample and, after suitable washes, excess of a second, enzyme-labelled antibody directed against the other end is added. After further washes, the enzyme activity is determined. This provides a direct measure of the amount of antigen present and has been applied to the assay of both rat and human alpha foetoprotein (Maiolini & Masseyeff *J. Immun. Methods* **8,** 223; 1975).

A variation of the above is to add an excess of enzyme-labelled second antibody directed against the first. This has the merit that, for example, an enzyme-labelled goat anti-rabbit gamma globulin sera can be used for all assays based on rabbit first antibody.

In conclusion, it seems unlikely that the use of isotopically-labelled reactants will be replaced in the near future for assays requiring extreme precision or sensitivity in the pmol l^{-1} range. In our experience EIA has proved somewhat more complex, taken longer to perform and has been slightly less precise than RIA. However, EIA and related techniques have an important part to play in the developing world, in countries with severe restrictions on the use of radioisotopes; for such yes/no cases as the diagnosis of pregnancy or detection of Australia antigen (a marker of past or current infection with hepatitis) and, finally, for hapten assays in which their use avoids the need for a separation step. □

The puzzles of Hercules

from James Pringle

About a dozen pulsing X-ray stars have now been discovered. Among these perhaps the most intriguing, and certainly one that has stimulated much research and headache is the star Hercules X-1. This has an X-ray luminosity of around 10^{37} erg s^{-1} and the X radiation is pulsed with a period of 1.24 s. Almost as soon as this pulsing was discovered, the pulse period was found to vary in a sinusoidal manner with a period of 1.7 d. This, together with the fact that the X radiation from Hercules X-1 disappears for 9 h once every 1.7 d, indicated that the pulsing X-ray star was in orbit around a companion star. The sinusoidal variation of the pulse period is due to Doppler shift of the intrinsic pulse period as the source orbits its companion, and the regular disappearance of the flux is due to eclipses. These ideas were confirmed by the discovery that the companion star was the already known variable star HZ Herculis. The side of HZ Her facing the X-ray star is so intensely heated by the X radiation, that as the binary star system revolves the apparent optical brightness of HZ Her varies by a factor of four with a period of 1.7 d.

It is generally accepted that Hercules X-1 is a neutron star which has a very strong magnetic field. A field strength of around 10^{12} gauss, similar to those deduced for radio pulsars, is anticipated. The X-ray luminosity is produced by material, stripped off the surface layers of HZ Herculis, being accreted by the neutron star. A neutron star (radius about 10 km) is so compact that material falling onto it releases about 10–20% of its rest mass energy when it strikes the stellar surface. Thus a small trickle of material can give rise to a considerable luminosity. Material accreting onto the star is highly ionised and is therefore channelled along the stellar field lines down onto the magnetic polar caps. Thus the accretion energy is liberated in two hot spots, each about a kilometre in diameter, on the stellar surface. Such a high luminosity radiated from such a small area can only be emitted as X radiation. Then if the magnetic axis and the rotation axis of the star do not coincide, a stellar rotation period of 1.24 s ensures that the emitted radiation is pulsed at the correct period.

Although these basic ideas have been around for some time, the details of the radiation processes have proved too complicated for reliable predictions of pulse shapes and pulse spectra to be made. There are many uncertainties concerning the emission of radiation at the polar caps, in particular because the radiation emitted by the material striking the surface interacts with the column of accreting matter on its way out. It is also unclear exactly where the accreting material releases most of its energy, whether at the base of the accretion column at the stellar surface or more gradually as the column settles slowly supported by radiation pressure. The velocity of the material that is emitting or interacting with radiation is also important since infall velocities can be as high as half the speed of light and relativistic effects can come into play. In such a strong magnetic field the electron orbits perpendicular to the field direction are quantised with levels separated by an energy $13 B_{12}$ keV, where B_{12} is the field strength in units of 10^{12} gauss. Thus quantum calculations of the emission and absorption processes have to be made for the role of cyclotron radiation in such strong magnetic fields.

A further complication has been introduced by a recent suggestion that the beam pattern of X-ray emission may be produced not so much by anisotropic processes occurring near the stellar surface, but rather by a shell of material at the Alfvén radius or the surface of the magnetosphere (of radius about a thousand stellar

---

James Pringle is at the Institute of Astronomy, University of Cambridge.

radii) which has collected there before being channelled down to the magnetic poles. If the shell of material is not spherically symmetric—a likely event given the expected dipolar shape of the magnetosphere—then the variation in the amount of scattering or absorption of X rays in passing through the shell in the direction of Earth as the star and shell rotate can give rise to an apparent pulsed emission even if the neutron star produces a steady X-ray flux. In the absence of other information it was beginning to seem as if little progress could be made in the unravelling of these various effects.

Some recent observations, however, have given some cause for hope. At the Eighth Texas Conference held in Boston in December 1976 (see *News and Views* **265**, 402; 1977) J. Trümper announced evidence for a strong cyclotron emission line in the hard X-ray spectrum of Her X-1 in data obtained from a balloon-borne experiment. The apparent line is at 53 keV which if assumed to be cyclotron emission corresponds to a magnetic field strength of $4{\cdot}6\times10^{12}$ gauss. Because of background subtraction problems, this line although apparent in the raw spectral data, is more clearly visible when the data has been processed. The processing involves taking the spectrum of those photons received during the peak of the pulse, and subtracting the spectrum of the rest from it. In this way the background (assumed not to vary with a 1.24 s period) is removed. If the data is interpreted as for the most part a steady flux from the source, on which is superposed a fully modulated pulsed flux, then the spectrum obtained by this method is that of the pulsed flux. If this is not the correct interpretation then there are problems in deciding what the subtracted spectrum actually represents.

A paper by Coe *et al.* in this issue of *Nature* (page 508) reports confirmation of Trümper's results. The observations were made using the Ariel 5 satellite. Background subtraction is less of a problem with the satellite data, but even so the confirmed line seems to have shifted to 64 keV and the authors do not comment on the statistical significance of their result.

Nevertheless, the observations should provide a much needed clue to the X-ray emission processes occurring in Hercules X-1 and the other pulsed sources. Further observations—for example another balloon flight by Trümper's group this autumn with a larger area detector—are underway; thus not only do theorists have something to start thinking about but also the prospect, welcome or not, of a more rigorous test for any ideas they may come up with. ☐

Towards some enzyme mechanisms

from C. C. F. Blake

In the heady days of the late 1960s, when X-ray diffraction began to reveal the structures of enzymes in atomic detail, it seemed that the comprehensive view of the active site and the binding of substrate analogues that the technique provided, would lead rapidly to the establishment of a mechanism for each enzyme that was studied. In rapid succession proposals for the catalytic mechanisms of lysozyme, chymotrypsin and carboxypeptidase were put forward that contained profound insights into the chemistry practised by hydrolytic enzymes. However, since that time, as attention has become focused largely on the intracellular metabolic enzymes, the regular reports of the structures of new enzymes have not been accompanied by the expected mechanistic breakthroughs. Not altogether unexpectedly, it is beginning to look as though the non-hydrolytic enzymes are not going to yield the secrets of their activity as readily as the hydrolytic enzymes. This rather disappointing picture has recently been relieved to some degree by proposals on the catalytic mechanisms of two 'second generation' proteases.

The first protease, thermolysin, is a member of the family of neutral endopeptidases that require zinc for activity. Following their work on the structure of the enzyme (Matthews *et al. J. biol. Chem.* **249**, 8030; 1974) which revealed that its polypeptide chain was organised in quite a different manner from the other known zinc-requiring protease, the exopeptidase carboxypeptidase, Matthews and his colleagues have now proposed that despite this difference the mechanism of thermolysin is very similar to that of carboxypeptidase (Weaver *et al. J. molec. Biol.* **113**, 119; 1977). The mechanistic proposals are largely based on an examination of the binding of the potent inhibitor Phosphoramidon (N-(α-rhamnopyranosyl-oxyhydroxy-phosphinyl)-L-leucyl-L-tryptophan). Phosphoramidon is located in the active site of thermolysin with one of its phosphinyl oxygens located 2 Å from the essential zinc ion, completing its tetrahedral environment, while the other oxygen hydrogen bonds to the carboxylate of Glu 143. The leucine residue of the inhibitor is located in a hydrophobic pocket that appears to represent the specificity site of the enzyme, accounting for its known preference for bulky aromatic residues on the amino side of the scissile bond. A number of small conformational changes occur on binding but they are restricted to the active site region.

On the basis of the binding of Phosphoramidon, and some dipeptide inhibitors, Matthews concludes that the phosphinyl compound acts as an analogue of the presumed tetrahedral transition state intermediate of the enzymatic reaction. This has enabled a detailed model of the transition state of the true extended polypeptide substrate to be built into the active site, leading in turn to the proposed mechanism. The major features of the substrate binding are: the location of the carbonyl oxygen of the scissile bond as the fourth zinc ligand; the location of the large hydrophobic residue on the amino side of the scissile bond in the specificity site; and an extensive antiparallel β-sheet interaction between the polypeptide chains of the bound substrate and the enzyme. On either side of the susceptible bond are a carboxyl group (Glu 143) which, together with an associated water molecule, is 'buried' by the substrate, and His 231 that forms a hydrogen-bonded pair with Asp 226, rather like the charge relay in the serine proteases. The proposed mechanism indicates that Glu 143 promotes the nucleophilic attack of the buried water molecule on the carbon of the polarised carbonyl group of the substrate, forming a tetrahedral intermediate, and concerted with this step, or following it, His 231 donates a proton to the nitrogen of the scissile bond, leading to its collapse. This mechanism is very similar to one of the two alternative mechanisms proposed by Lipscomb for carboxypeptidase (Lipscomb *et al. Brookhaven Symp. Biol.* **21**, 24; 1968), except that proton donation is carried out by the histidine in the 'charge relay' rather than a tyrosine residue. By reverse analogy, it can be argued that the thermolysin mechanism supports the proposal that Glu 270 promotes the attack of a water molecule on the substrate carbonyl in the carboxypeptidase mechanism, against the alternative of direct nucleophilic attack by the glutamic acid.

Precisely the same argument is used in the case of the second protease, penicillopepsin. The three-dimensional structure and amino acid sequence of this enzyme were reported recently (Hsu *et al. Nature* **266**, 140; 1977), clearly demonstrating it to be a member of the acid proteases; the last major family of proteases to be examined by X-ray diffraction. Now James and his

---

C. C. F. Blake is a lecturer in Molecular Biophysics at the University of Oxford.

colleagues (James *et al. Nature* **267**, 808; 1977) have immediately followed the description of the structure with a proposal for the enzyme's mechanism —just like the old days! This proposal is based largely on the remarkable environment of the two essential acid groups, Asp 32 and Asp 215, although binding studies have been carried out on the potent inhibitor 1,2,epoxy-3-(p-nitrophenoxy) propane (EPNP). The difference map of inhibitor binding shows that the two molecules of EPNP have reacted covalently with penicillopepsin, one with the carboxyl group of Asp 32, the other with the carboxyl group of Asp 215. Associated with inhibitor binding is clear evidence of a conformational change to Tyr 75 that brings it into the active site.

The key to the mechanism of the acid proteases seems to reside in the environments of the two acid groups. Asp 32 is located in an unusually tight hydrogen bonding net, that involves its carboxyl group in interactions with (1) the carboxyl of Asp 215, (2) the hydroxyl of Ser 35, (3) the main-chain NH of Gly 217, (4) a bound water molecule, and (5) the main chain atoms of the 32–33 and 33–34 peptide groups. This complex of interactions makes Asp 32 inaccessible for the formation of covalent interactions with substrates without conformational changes in the active site, which its particular structure seems to rule out. Asp 215 is on the other hand rather more accessible, but since it seems established that this group has the higher *p*Ka, it is unlikely to be the attacking nucleophile.

James points out that the resolution of this problem may be sought in the cluster of polar and ionic side chains that lie in the hydrophobic core near the two acid groups. These include Asp 304, which makes hydrogen bond contact with the main chain carbonyl of Thr 216 (the same peptide whose NH hydrogen bonds to Asp 32), nearby is an ion pair, Lys 308 and Asp 11, which has as neighbours a buried tyrosine, residue 14, and a surface histidine, residue 57. With the exception of the histidine, all these residues are conserved in porcine pepsin. This cluster of buried residues is interpreted as an extended charge relay system. It is assumed that the binding of substrate in the large cleft of the enzyme will affect two associated hairpin loops carrying Asp 11 and Tyr 75, causing a minor conformational change to the former and a larger one to the latter, similar to that observed when EPNP reacts with the two acids, bringing Tyr 75 into the active site. The movement of Asp 11 would disrupt its ion pair interaction with Lys 308. A series of changes then ensues that involves Lys 308 pairing with Asp 304 and the protonation of the 216–217 peptide bond that would enhance the electrophilicity of the proton shared between Asp 32 and Asp 215 This proton could then function to polarise the carbonyl group of the substrate in a mechanism that is otherwise identical to the zinc-carbonyl mechanism of carboxypeptidase. Asp 32, the analogue of Glu 270 in carboxypeptidase, would promote the attack of its bound water molecule on the carbon atom of the polarised carbonyl group of the substrate, while Tyr 75, the analogue of Tyr 248 in carboxypeptidase, protonates the nitrogen of the scissile bond. Thus in James's view the mechanism of the acid proteases is essentially the same as that of carboxypeptidase, with modifications to make it competent at a low *p*H. This means replacing the Lewis acid, Zn^{2+}, with a proton whose electrophilicity is enhanced by the charge relay involving the protonated peptide, and the placing of Asp 32 in an unusual environment to keep it in the ionised state at very low *p*H.

Although the mechanism of the acid proteases proposed by James has some controversial features, not least the involvement of a peptide bond, the remarkable environment of the essential acid groups will provide a solid basis for any further discussion, and this is what the X-ray crystallography of enzymyes should be all about. ☐

Visiting Halley's Comet

from David W. Hughes

COMETARY missions have been discussed in varying degrees of detail on both sides of the Atlantic for well over a decade; spacecraft have been chosen, experiments have been planned, data and science returns estimated, impact hazards evaluated. All this as yet to no avail. Why? Comet trips are not cheap; $100,000,000 is a reasonable bargain-basement estimate. Also they represent a distinct new start in space exploration, needing new people and new ideas and the old teams of lunar, planetary and magnetospheric space scientists seem only too willing to plump conservatively for well tried experiments or at best minor advances in techniques. Also when the budget for space exploration is limited, the 'jobs for the boys' and 'let's play safe' syndromes come to the fore.

Comets are also minor objects in the Solar System. They are studied by a keen but small band of scientists. Very few of them get into the news, comet Kohoutek being the only one to make a stir recently and this disappointed most tax paying (and consequently space exploration supporting) people by being much fainter than originally predicted. The missions are also difficult; comets, being small, are hard to find and considerable launch and trajectory correction accuracy is required to get close to them. Ballistic transfer usually gives a fly-by speed of upwards of 7 km s^{-1}. Measuring the properties of a cometary coma and nucleus when you are flying by at 25,000 km h^{-1} is not easy and also the time during which cometary phenomena are being investigated makes up a very small percentage of the total mission time (however the same could easily have been said of the first Mariner trips to Mars and Ranger trips to the Moon).

How does comet Halley change all this? First, it has the advantage of being famous. Second, it has been around a long time. It passes perihelion about every 76 yr, is unusually bright and seldom goes unnoticed. Observations go back as far as 239 BC when it was mentioned in ancient Chinese records and it has been seen 28 times since. Third, it is rather awkward to get to, its retrograde orbit giving a ballistically transferred spacecraft a fly-by speed of almost 60 km s^{-1}. Halley is therefore an ideal candidate for a rendezvous mission, but this would require considerable expenditure of power. Ion drive and solar sail propulsion have been suggested as ways round this problem.

These two mechanisms are still at the theoretical stage but have caught the imagination of space technologists to such an extent that Halley's comet is being actively suggested as a first mission application for the two competing techniques. Scientifically, Halley's comet is as good a start as any to a programme of cometary investigation. The first mission must be regarded as the precursor to a series of investigations which will eventually take in comets of diverse qualities and build up a complete picture of the family. The exact form of the cometary nucleus is still a mystery and there is debate as to whether it is a condensed, dirty, icy snowball or a large swarm of smaller particles. Comets decay to produce meteor streams and so feed the zodiacal dust

---

David W. Hughes is a lecturer in the Department of Physics at the University of Sheffield.

cloud. Cometary chemistry is very similar to that of interstellar gas but fortunately comets are closer. The interaction between the plasma in the cometary coma and the high speed magnetoplasma of the solar wind poses exciting physical problems. Comets are also probably in the form of the original condensate from the pre-Solar System nebula and as such furnish an outstanding clue in cosmogony.

Halley's comet was visible to the naked eye over a four month period at its 1910 apparition. The nuclear region was several thousand kilometres in diameter but on 18 May, 1910, when Halley transited the Sun, no solid nucleus was observed against the solar disk indicating that, if this existed, it must be less than 50 km across. The coma was about 3×10^5 km in diameter during the postperihelion phase, and had a continuous background spectrum with superimposed CN and C_2 lines. Transient phenomena were observed in the inner coma regions. Halley is a very dusty comet and also has non-gravitational effects acting on its nucleus leading to a lengthening of the orbital period by about 4.1 d per apparition.

The main scientific objectives of the fly-by are to image the nucleus, to find its size, shape, rotation period and colour, to determine the nature of the multiple condensations seen in 1910, to determine the abundance and spatial distribution of neutral molecules, radicals and charged particles in the coma and tail, to investigate the shockwave interaction between the cometary plasma and the solar wind, to measure the spatial density and size distribution of the emitted dust particles and to investigate the time variation of the coma's structure and brightness.

Opportunities for ballistic missions to Halley have been studied by Robert W. Farquhar and William H. Wooden II (NASA Goddard Space Flight Centre) and have been recently reported in NASA Publication No. X-580-77-46. At a fly-by speed of $60\ \mathrm{km\ s^{-1}}$ the spacecraft will pass through the inner and outer coma in 14 and 18 min respectively. The miss distance from the nucleus would be about 2,000 km. The spacecraft could approach closer to the nucleus with onboard navigation but previous visual observations indicate that Halley has multiple nuclear condensations and it would be difficult to know which one to pick when the spacecraft is a considerable distance from the comet. At perihelion Halley is about 0.59 a.u. from the Sun. Perihelion passage occurs on 10 February, 1986 and most investigating spacecraft plan to visit Halley within a period of about 60 d either side of this date.

Rendezvous with Halley

Farquhar and Wooden put forward four possible missions. The first is a dual launch around 4 July, 1958 of the spacecraft using a single Space Shuttle, one planned to intercept Halley 63 d before perihelion (at 1.37 a.u.) the other 39 d after perihelion (at 1.00 a.u.). One approaches Halley from the sunward side the other from the anti-Sun direction. The second senario again uses the Shuttle to launch two spacecraft, this time on 10 March, 1985. One intercepts Halley 58 d before perihelion passage, the other flies off to intercept two other comets, Giocobini-Zinner on 11 September, 1985 and Borelly on 25 December, 1987 these interceptions taking place at 1.03 and and 1.36 a.u. respectively. The third launches the spacecrafts at Halley in a trajectory that returns to Earth after passing the comet. They then swing past the Earth and are retargeted on Borelly to fly-by in January, 1988 or comet Tempel-2 in September, 1988. The final proposed mission has a dual launch in August, 1985, with both spacecraft encountering Halley at the same time, one passing the nucleus on the sunward side at a distance of about 2,000 km and the other moving through the tail about 30,000 km behind the nucleus.

The Warsaw-Moscow soil structure project

from I. J. Smalley

A JOINT programme to provide a set of soil structure standards for use in engineering geology and soil mechanics has been under way for five years at the Universities of Warsaw and Moscow and is now nearing completion. The first applications of the scanning electron microscope (SEM) to soil structure studies were made in the late 1960s and in 1971 a project was initiated by B. Grabowska-Olszewska of the Warsaw University Engineering Geology Institute and V. Osipov and V. Sokolov of Moscow University with the aim of providing a complete range of reference structures from clay sediments of different ages and from different sedimentary environments.

The scanning electron microscope has not proved as effective a tool in the investigation of soil structures as was hoped when studies began and much of the earlier enthusiasm is now waning. There is, however, a growing emphasis in engineering geology and soil mechanics on the study of earth materials in some detail and Attewell and Farmer (*Principles of Engineering Geology*, Arnold, 1976) and J. K. Mitchell (*Fundamentals of Soil Behaviour*, Wiley, 1976) in their new books both present extensive sets of soil microstructures, but they are essentially illustrations; the relating of soil structure to engineering properties has not been achieved. A set of standard structures with related properties may help in the making of this necessary connection.

The Warsaw-Moscow project has been hampered by the lack of SEM facilities in Poland and the USSR and most of the structural photographs were obtained using the American built 'Cwik-Scan' 106A SEM of Moscow University. Samples were taken from Poland and the European USSR and all geological areas are represented from Proterozoic to Holocene. The programme involved the examination and testing of 86 samples of eluvial, hydrothermal, marine, lacustrine, alluvial, glacial and glacial-lacustrine origins. Five structural elements were identified: primary clay particles, micro-aggregates, aggregates, grains and inclusions of microfauna, microflora and microcrystals of salts and ore minerals. The structural data, usually presented as 5000× and 500× photographs, is supplemented by a range of property measurements including specific gravity, water content, density of wet soil, porosity, specific surface, liquid limit, plastic limit, uni-axial and pure shear strengths and it is the relation of this set of mechanical data to the structural representations which makes the project so valuable.

E. M. Sergeev (Moscow) and W. C. Kowalsky (Warsaw) have editorial attachment and various western investigators have been involved; in particular David Krinsley of Arizona State University, doyen of the SEM sand gazers, has recently been in Warsaw helping with the final stages of the project; and R. Pusch of Lulea University has been giving encouragement. The 1973 Gothenburg Engineering Soil Structure Symposium organised by Pusch revealed the disorder and confusion in the field; perhaps the Warsaw-Moscow project will provide a necessary foundation for future studies.

I. J. Smalley is a lecturer in the Department of Civil Engineering at the University of Leeds.

All these ballistic missions would produce an enormous amount of fascinating new data concerning comets and they have the advantage of a late launch date so that the orbital parameter of the comet can be updated by observations taken as it comes towards the Sun. They also have a short transit time, the spacecraft usually encountering the comet about 8 months after launch. Launch energies are also relatively low, C_3 being around 12 km^2 s^{-2} for the missions that do not have an Earth return and about four to five times this for the one that does. One disadvantage is the high fly-by speed, most spacecraft encountering Halley nearly head on

Solar sails and ion drive

Two rather unorthodox schemes have been proposed recently to get over this problem Both require advanced propulsion capabilities and these capabilities have been little developed to date. Both require flight times around 3 to 4 yr and thus need launch dates in early 1982. Both schemes have the enormous advantage of enabling the spacecraft to rendezvous with the comet and move off with Halley on its journey away from the Sun.

J. L. Wright (Jet Propulsion Laboratories, California) and J. M. Warmke (Battelle Columbus Laboratories, Ohio) discuss the solar sail concept in the *American Institute of Aeronautics and Astronautics* paper number 76–808. Here a sail, between 300 and 800 m across, would be attached to an existing spacecraft, like Mariner or Pioneer, the propulsion force being derived from the reflection of solar photons About 0.9×10^{-5} N m^{-2} could be obtained at 1 a.u. By tilting the sail with respect to the Sun's direction the spacecraft could tack on an inward or outward trajectory. No additional propellant is required; one literally sails through space. At 1 a.u. a typical spacecraft could be accelerated at between 0.2 and 1.3 mm s^{-2}, corresponding to a mass loading on the sail of between 40 and 60 g m^{-2} Wright and Warmke suggest that with considerable development effort the sail could be ready for a first mission application in late 1981. 640,000 m^2 of sail could accelerate a 800 kg spacecraft to Halley. Launch would be around January, 1982 the vehicle first spiralling inward to about 0.3 a.u then being cranked into an orbit of inclination 162° Gaining energy it would move out to about 2 a.u. before returning to the inner Solar System nearly along Halley's orbit, rendezvousing with the comet after perihelion somewhere between 1 and 2 a u from the Sun

The second scheme uses an advanced form of solar electron propulsion and has been put forward by K. L. Atkins (Jet Propulsion Laboratories) and C. Terwilliger (Boeing Areospaces Co) in *AIAA Paper* 76—1069. They note the massive advance in electron propulsion performance. 1973–74 vintage required 50 kg of spacecraft systems to produce a kilowatt of power. New 3-mm thick solar cells and high powered, direct-drive ion engines have reduced the specific mass to 10 kg giving a fivefold increase in power to weight. To get to Halley the spacecraft would be launched around April, 1982 in an outbound flight towards Jupiter. The ion drive vehicle remains outside Halley's flight path, makes a powered 'U-turn' at about 4.5 a.u and speeds back towards the Sun essentially already in Halley's orbit, simply waiting for Halley to overtake. Flight time is around 3.75 yr, rendezvous occuring about 50 d before perihelion and maximum cometary activity. The spacecraft then stays with Halley having in Atkins and Terwilliger's words "a pre-performance seat to watch the whole show"

Halley is even now coming in towards the Sun and has already passed the orbit of Uranus. It is hoped that we can be adventurous enough, both scientifically and financially, to get one of the schemes outlined above ready to meet it as it comes by in 1985–86· if not we will have to sit back until 2026. □

Environmental mutagenesis

from Margaret Fox

The 2nd International Conference on Environmental Mutagenesis was held at Edinburgh on 10-16 July, 1977.

A CENTRAL problem in the field of environmental mutagenesis is to design 'short-term' tests, using either prokaryotic or eukaryotic systems, or both, capable of detecting many different types of genetic damage. During the conference the deficiencies and advantages of the currently available tests were extensively discussed.

Carcinogens in most instances have produced positive results in screening programmes for mutagens in contrast to non-carcinogens (B. N. Ames *et al.*, University of California, Berkeley) and it seems likely that DNA damage is intimately involved in both cases. However, there are some notable exceptions to this rule. M. S. Legator (Department of Preventative Medicine, University of Texas) in discussing microbial activation systems such as Ames's *Salmonella* test, pointed out that not only do such systems fail to detect certain types of genetic damage, for example, chromosome non-disjunction, they also fail to detect several other classes of known mutagen and carcinogen such as ionising radiation, chlorinated pesticides, azo dyes and certain metal carcinogens.

The necessity for metabolic activation of many carcinogens is now well established, and S-9 preparations of rat liver microsomes are now routinely included in many screening tests. The almost exclusive use of liver preparations and the assumption that the inclusion of liver microsomes in microbial systems will accurately mimic *in vivo* mammalian metabolism was criticised.

Clear evidence for a difference between bound products in mammalian and prokaryotic DNA was presented by A. Dipple and coworkers (Frederick Cancer Research Centre, Maryland). Incubation of ^{3}H-7-12-dimethyl benz[a]anthracene (^{3}H-DMBA) with cultured mouse embryo cells resulted in at least three identifiable DNA reaction products whereas only one of the three was identifiable when two of Ames's *Salmonella* strains were incubated with ^{3}H-DMBA in the presence of liver microsomes. Because of such deficiencies in prokaryotic test systems, increasing attention is now being paid to eukaryotic and in particular to mammalian systems.

For risk estimates it is important to have precise knowledge of dose–response relationships, and a direct approach to this has been made in several laboratories by the use of cultured human fibroblasts. V. Mayer (Michigan State University) presented data indicating a threshold or no-effect dose for mutation to 8-azaguanine resistance after exposure of human fibroblasts to ultraviolet and some reactive hydrocarbon derivatives. The implications of these observations are of such importance that it is essential they be validated in other laboratories and for other loci, particularly in view of the fact that alterations in methodology can profoundly alter the shape of the dose–response curve for mutation to 8-azaguanine resistance in V79 Chinese hamster cells (S. McMillan, Paterson Laboratories, Manchester) Linear dose–response curves with no threshold have been found for several mutagens tested at both the HGPRT and TK locus in mouse L5178Y cells (A. Knapp, Department of Radiation Genetics and Chemical Mutagenesis, Leiden) and for 8-methyoxypsoralen plus near ultraviolet light tested at the

HGPRT locus in V79 cells and human diploid fibroblasts (J. Simons, Department of Radiation Genetics and Chemical Mutagenesis, Leiden).

8-methyoxypsoralen (8-MOP) plus long wave ultraviolet light is an effective treatment for psoriasis, a debilitating skin disease in man. 8-MOP in the dark is an effective frameshift mutagen in *Escherichia coli* and *S. typhimurium* (B. Bridges, MRC Cell Mutation Unit, University of Sussex). In contrast, base pair substitution mutagenesis occurs after exposure to 8-MOP plus near ultraviolet light. 8-MOP plus near ultraviolet light is mutagenic in both V79 cells and human diploid fibroblasts when assayed at the HGPRT locus (Simons), but no ouabain-resistant mutants could be recovered in V29 cells (C. Arlett, MRC Cell Mutation Unit, Sussex). 8-MOP in the dark does not seem to increase the frequency of sister chromatid exchanges in human lymphocytes *in vitro* although 8-MOP plus near-ultraviolet had a positive effect (A. Brøgger, Norsk Hydro Institute, Oslo). Many assumptions have to be made to estimate risk from such data and essentially negative results for induced chromosome aberrations in lymphocytes of psoriasis patients undergoing treatment have been reported by Brøgger. However, the treatment should be regarded as potentially hazardous although the benefit to individual patients may well offset the overall risk.

Several presentations discussed completely *in vivo* 'short-term' methods for assay of induced somatic mutation in mammals. Mice heterozygous for the *dilute* and *leaden* loci irradiated late in foetal life show patches of abnormal pigment cells when whole mounts of epidermis are made shortly after birth (A. G. Searle, MRC Radiobiology Unit, Harwell). Such changes, the result of recessive mutations at the two coat colour loci, are observable at the cellular level as alterations in the shape of and pigment density in melanocyte precursor cells.

Possible pitfalls in the use of this method were discussed by L. B. Russel (Oak Ridge, Tenessee) who emphasised the need for microscopic scoring, as coat colour spotting on a macroscopic level can be the result of other nonspecific effects of mutagen exposure such as decrease in number of precursor cells and/or disturbances in differentiation. With careful attention to such problems, induced mutant frequencies for a number of test compounds roughly paralleled but were significantly higher than those found for germ cell mutations (specific locus test), suggesting that possibly different types of genetic damage are being assayed.

In vivo exposure of animals to mutagens followed by *in vitro* assay is relatively rapid, organ and tissue-specific effects can potentially be monitored, and the approach has the advantage that injected compounds are subjected to full metabolism and detoxification. Using this approach, B. Dean (Shell Research, Sittingbourne) demonstrated increased frequencies of 8-azaguanine and ouabain-resistant clones in cultured cells derived from different tissues of 3-week-old Chinese hamsters previously treated with ethyl methanesulphonate, methyl nitrosourea and diethylnitrosamine.

In vivo exposure and *in vitro* detection is the principle on which monitoring of exposed human populations by scoring chromosome aberrations in lymphocytes is based. For accurate assessment of induced damage it is important that aberrations be scored in the *first* metaphase after phytohaemagglutinin stimulation. It is now possible to identify first metaphase exactly by culturing lymphocytes in BUdR and identifying second divisions as showing differential staining of chromatids. Using this method, Grossen (Christchurch Hospital, New Zealand) demonstrated that by 48 h, the usual sampling time used, all cultures of lymphocytes examined showed second divisions (range 2–53%). The scoring of such a heterogeneous population could lead to erroneous conclusions with respect to overall sensitivity.

The *in vivo/in vitro* approach was also adopted by R. Albertini (University of Vermont Medical College). This method of mutagen detection, based on autoradiographic measurements of the frequency of phytohaemagglutinin-stimulated lymphocytes which continue to incorporate ^{3}H-thymidine in the presence of 6-thioguanine (6-TG), was validated by the demonstration of a high frequency of such cells in patients suffering from Lesh-Nyhan disease and known to lack HGPRT activity. Significantly higher frequencies of 6-TG resistant lymphocytes were demonstrated in patients receiving cancer chemotherapy. The molecular basis of the 6-TG resistance in this system is at present unknown, but the authors invoke somatic mutation and suggest that the assay could be used in parallel with cytogenetic screening for monitoring genetic damage.

Overall the general feeling was that as yet no single test or panel of tests can accurately predict potential hazards to man, and that 'short-term' tests, particularly in microorganisms, although offering the possibility of rejecting dangerous chemicals at an earlier stage cannot yet completely replace conventional carcinogenic tests with animals.

The concern of industry and the scientific community in this field is indicated by the recent formation of the International Commission for Protection against Environmental Mutagens and Carcinogens (ICPEMC) under the Chairmanship of Professor S. Sobels (Leiden) to act as an advisory body and collate data on an international level. In this way it is hoped that progress can be made in protecting man from his hazardous environment.

Recombination at Nethybridge

from a Correspondent

The fourth bi-annual EMBO Workshop on the Molecular Basis of Genetic Recombination was held at Nethybridge, Scotland, on 20-25 June, 1977. As on previous occasions, a deliberate attempt was made by the organisers to bring together scientists working on a very wide range of recombination systems.

An essential intermediate in recombination is hybrid or heteroduplex DNA, which may alter its length by branch migration. This involves the breakage and formation of hydrogen bonds between complementary bases at the point where polynucleotide chains exchange pairing partners. For the first time, exact measurements of the rate of branch migration *in vitro* have been made by R. Warner (University of California, Irvine) and C. Radding (Yale University) using φX174 or G4 phage recombination intermediates. The rate of branch migration seems too low to explain the spontaneous formation of long stretches of hybrid DNA *in vivo* and it is therefore likely that the process is driven by enzymes or DNA binding proteins. Electron microscope studies of recombination intermediates in phage PMB-9 by D. Dressler (Harvard University) demonstrate the formation of reciprocal hybrid DNA in molecules held together by a symmetrical strand exchange point. This is dependent on the *rec*A function of *Escherichia coli,* but independent of *rec*B.

Predictions of the Aviemore model of genetic recombination (proposed by M. Meselson and C. Radding at the second EMBO Recombination Workshop in 1973) were confirmed by experiments in *Ascobolus* reported by J-L. Rossignol (Université de Paris, Orsay). The model states that recombination is initiated by an asymmetric strand transfer followed by rearrangement, or isomerisation, of polynucleotide chains to give hybrid DNA on two chromatids. The location of hybrid DNA can in part be determined by examining the pattern of gene conversion and post-meiotic segregation (PMS) of individual markers in meiotic octads. Examination of mutants at increasing distances from the point where recombination is initiated, shows that there is an increase in the proportion of aberrant 4 : 4 octads, which have two PMS events and can only arise from reciprocal hybrid DNA. Furthermore, among a class of mutants that show unequal numbers of 6 : 2 and 2 : 6 segregations (gene conversions), the disparity increases with distance from the initiation point of recombination, and Rossignol was able to show that this is expected if hybrid DNA is initially asymmetric, but is later symmetric. In studies on the correction of mismatched bases in hybrid DNA, P. Pukkila (National Institute for Medical Research, Mill Hill) constructed artificial heteroduplex molecules from φ80 phages containing mutant or wild type tRNA^{Tyr} genes of *E. coli.* Since the tRNA sequences are known, it is possible to construct molecules with known base mismatches. The enzyme DNase 1 from *Ustilago,* which is implicated in gene conversion, cleaves these molecules at or near the mismatch, but surprisingly, purine/pyrimidine mismatches can be a better substrate than other mismatches. In collaborative studies with M. Meselson (Harvard University), M. Radman (Université Libre, Brussels) reported experiments which may explain the biological function of the mismatch repair system. λ phage heteroduplexes were constructed in which one strand was methylated and the other was not. The *in vivo* correction system appears to remove the mismatched base in the non-methylated strand. The significance of this observation is that newly replicated DNA is non-methylated and therefore the errors in DNA synthesis will be preferentially corrected to wild type. PMS is due to the failure to correct mismatches in hybrid DNA, and R. Holliday (National Institute for Medical Research, Mill Hill) described a new method in *Ustilago* for detecting PMS without tetrad analysis, which may facilitate the search for mutants lacking this particular repair function.

The pairing of chromosomes at meiosis is mediated by an organelle known as the synaptonemal complex (SC). A. Carpenter (University of California, San Diego) described the accumulating evidence in *Drosophila* that electron-dense nodules on the SC are the sites of crossing over. Meiotic mutants with altered frequency or distribution of cross overs have corresponding changes in nodule formation. In the silkmoth *Bombyx,* S. Rassmussen (Carlsberg Laboratory, Copenhagen) reported that nodules are absent from the SC of females where there is no crossing over, but present in males which do recombine chromosomes.

Studies in bacteria of insertion sequences (IS), transposons and phage mu have opened up a new field of *rec*A independent recombination events that do not require significant sequence homology. However, the sequence at the ends of a given element (which are often inverted repeats) is essential for the recombinational event promoted by this element. Recent results with IS (J. Besemer, University of Cologne) transposons (N. Kleckner, Harvard University) and phage mu (A. Bukhari, Cold Spring Harbor, New York, and P. Van de Putte, University of Leiden) have shown that in all these systems excision of the element is usually associated with the formation of deletions or substitutions. IS and transposons seem to have preferred regions of integration although there are a number of insertion sites within a given region. It was previously known that integration into host chromosomes is an essential step in the lytic cycle of phage mu, but new isotope experiments indicate that daughter molecules rather than the parental phage genome become integrated. Similarly on induction of a mu lysogen most of the original prophage remains in the chromosome, the daughter molecules being replicated from that template and then reintegrated elsewhere.

The biochemical basis of site-specific *int* mediated recombination has been established by the *in vitro* system of H. Nash described by L. Enquist (both of the National Institutes of Health, Bethesda). A λ circle containing two separated attachment sites, which has been supercoiled by DNA gyrase, is a substrate for reciprocal recombination mediated by the purified *int* protein. Enquist's own results indicate that short regions of hybrid DNA are formed during this type of recombination *in vivo* and that these can migrate from the attachment site if the adjacent region is homologous; in other words, *int* recombination is not absolutely site specific. The basic problem in recombination mediated repair is the mechanism whereby damaged DNA can seek out an undamaged homologous molecule. P. Howard-Flanders (Yale University) now has evidence for a 'transendonuclease' activity in *E. coli,* which is *rec*A dependent. In response to psoralen-damaged phage DNA, the enzyme introduces nicks into supercoiled homologous, but not heterologous DNA *in vivo,* as well as in an *in vitro* system. K. Powell (University of Newcastle-on-Tyne) reported that the *rec*A product in *E. coli* is protein X and that the *tif* mutant (which maps in the *rec*A gene) produces an X protein with altered electrophoretic mobility in a two dimensional gel system.

Chi mutants in bacteriophage λ are hotspots for recombination, mediated by the bacterial *rec* system. F. Stahl (University of Oregon, Eugene) has now examined λ genomes in which sequences of bacterial DNA have been inserted. Some of these contain naturally occurring *chi* sequences, whereas others do not. He estimates that there is one recombination hotspot for every ten or so bacterial genes. Mutants with properties similar to *chi* are also known in *Neurospora* and *Schizosaccharomyces,* and similar sequences probably occur naturally since it is known that recombination in fungi is distributed unevenly along the chromosome. Moreover, P. Thuriaux (University of Bern, Switzerland) came to the conclusion that recombination may be restricted to structural genes in higher eukaryotes, since neither total map distance of the genome nor the length of individual structural genes varies with DNA content. It is evident that the text-book dogma that recombination is distributed randomly along chromosomes is about to be finally dispelled, both in prokaryotic and eukaryotic organisms. □

A hundred years ago

The Dutch Geographical Society has received a report from the expedition recently sent out to explore Sumatra. One division left Padary in the middle of May for the mountainous centre of the island. They have successfully penetrated into these hitherto unknown regions, and describe them as of surpassing grandeur. The mountain sides are clothed to the very top with a most luxuriant forest growth, almost impenetrable to the sun's rays. The inhabitants consist of a few utterly degraded Malays gathered together in wretched villages. The health of the expedition is excellent.

review article

Interstellar molecules

B. Zuckerman*

Recently discovered interstellar molecules are a powerful new tool in the arsenal of the astrophysicist. Operating in a completely non-terrestrial environment, interstellar chemistry produces both everyday molecules likely to be found around the house and exotic species never before observed on the Earth. Interpretation of the molecular spectra requires an interdisciplinary approach.

MOST of the mass of our Milky Way Galaxy is contained in the stars. There is also a very cold and tenuous gas between these stars that comprises a small percentage of the total mass of the Milky Way. While not as visually spectacular as the stars and the bright emission nebulae this cold gas has, nonetheless, proved to be an exceptionally powerful tool for the study of such diverse astrophysical problems as cosmology, cosmogony, galactic structure, stellar evolution, star formation and nucleosynthesis. The cold gas, which is composed of atoms, molecules, and 'dust' grains (of uncertain composition), is most effectively studied by means of radio astronomical spectroscopy. Except for a few diatomic molecules, all of the 40-odd known interstellar molecules have been detected only by means of their radio spectra (Table 1). It seems that production, destruction and excitation of these molecules take place in a hostile (by terrestrial standards) environment by means of various processes involving atoms, ions, free radicals, molecular ions and neutral molecules, solid surfaces, cosmic rays and high and low energy radiation. With but one exception the radio spectra of all of the molecules in Table 1 have been detected within the past eight years. Data have accumulated extremely rapidly and the promise for continued rapid growth of the field is bright if large new antennae and interferometers sensitive to millimeter wavelength radiation are constructed. This fluid situation renders a definitive review impossible at this time. I will, here, describe only a few of the more interesting recent developments: those that are basically astronomical as well as those that involve close collaborative efforts among astronomers, physicists and chemists.

Interdisciplinary approach

The most important contribution of the laboratory spectroscopist to the radio astronomer is the measurement and assignment of molecular transition frequencies. Because most of the molecules in Table 1 are stable and have high vapour pressures at room temperatures, it is relatively easy to measure and assign their complete rotational spectra. The astronomer simply uses this type of information to search for and identify interstellar molecules. There are, however, molecules such as free radicals and molecular ions that cannot easily be studied in the laboratory because they are very unstable in laboratory conditions, and others that have very low vapour pressures at room temperatures. Many such molecules have been discovered by accident by radio astronomers who were searching for other molecules with known spectra. Even in the absence of any laboratory data tentative identification is often possible. Considerations of cosmic abundances of atoms, interstellar chemistry, calculations *ab initio* of molecular structures, isotopic substitution, and hyperfine structure when combined together are often sufficient to identify a molecule with considerable reliability. In this way interstellar HCO^+, N_2H^+ and HNC were all correctly identified before they were only very recently observed in the laboratory with new experimental techniques[1–5]. The international flavour of the field is highlighted by the nearly simultaneous observations of HNC in laboratories in the USA, West Germany and Australia[3–5]. The definite confirmation of the existence of HCO^+ and N_2H^+ in considerable abundances in interstellar molecular clouds show that ion–molecular reactions[6–7] must have an important, possibly the dominant, part in interstellar chemistry.

Because of the low kinetic temperatures (10–100 K) and gas densities (10^2-10^6 cm^{-3}) in most molecular clouds conditions are generally not those of thermodynamic equilibrium. The detailed population distribution in the rotational ladders of interstellar molecules can, in principle, be used to deduce the physical conditions in the clouds (especially the temperatures and densities of both neutral and ionised species). In practice one assumes that, at least microscopically, conditions are in steady state and collisional and radiative rates into and out of the various rotational levels are in balance. Radiative transition probabilities are generally well known. The most abundant constituents of molecular clouds are hydrogen molecules and helium atoms. Neither has a spectrum accessible to radio astronomy, but they play the dominant part in the collisional excitation of the less abundant polar molecules listed in Table 1. Unfortunately, little has been known about the magnitude of and selection rules for collisional transitions under low temperature interstellar conditions.

Recent quantum mechanical calculations[8–10] of collisional rates between He and HCN, CO and N_2H^+ have removed much of the uncertainty in this area. The propensity rules for the collisional transitions differ from the radiative selection rules and indicate differences between neutral–neutral and neutral–ion collisions as well. This allows the possibility of highly non-equilibrium population distributions, namely inversion (heating) and anti-inversion (cooling), in some rotational transitions. Sometimes this can lead to exotic phenomena such as the high gain SiO, H_2O and OH masers discussed below. Because of the very general competition between ordinary spontaneous radiation, and the simple collisions mentioned above, interesting phenomena can occur even over most of the volume of common molecular clouds.

Chemical history of the galaxy

Among the many astrophysical problems that can be investigated with interstellar molecules is the galactic history of the elements[11]. Stars return a significant percentage of their mass back to the interstellar gas out of which they were born. Red giants and even more evolved stars, such as planetary nebulae and supernovae, are very important participants in this interchanges of mass. The 'cooking' of hydrogen and helium into heavier elements such as carbon, oxygen, and nitrogen deep in the interior of giant stars and the subsequent expulsion of these elements back into interstellar space determines the chemical evolution of our Galaxy. Since it is believed that originally the Universe was composed almost entirely of hydrogen and helium, the formation of planets like the Earth and their living inhabitants is entirely dependent on this mass exchange between stars and gas.

Recent studies of relative isotopic abundances in various interstellar molecules, such as H_2CO, CO, HCO^+, HCN and CS[12-16], promise to help us unravel the long history of our galaxy. It seems, for example, that there may have been some enrichment of ^{13}C relative to ^{12}C and of ^{17}O relative to ^{16}O in the interstellar medium since the time our Solar System formed some 4.6×10^9yr ago. With the aid of theoretical calculations on stellar interiors, these observations may tell us about the types of stars that are responsible for the heavy elements found in the interstellar gas. For example, the apparent difference in the $^{15}N/^{14}N$ ratio between the central and outer portions of our Galaxy has been interpreted[15] to imply a greater proportion of low mass stars and a lesser proportion of supernovae near the galactic centre.

Unfortunately, a good deal of the interpretation is still beclouded by the possibility that isotopic fractionation effects are important in the formation and/or destruction of interstellar molecules[17]. Therefore, it may not be possible

Table 1 Known interstellar molecules as of January 1977

Number of atoms	Molecule	Optical/UV	Radio spectrum	Detected in astronomical objects*
2	H_2—hydrogen	✓	—	1, 2(?), 3
	OH—hydroxyl radical	✓	Λ-doubling	1, 2, 3, 4
	SiO—silicon monoxide		Rotational	2, 3
	SO—sulphur monoxide		Rotational	3

*1, Dark dust cloud; 2, circumstellar envelopes; 3, H II region and/or galactic centre; 4, external galaxies.

to measure directly the $^{13}C/^{12}C$ ratio simply by measuring, for example, the abundance ratio $^{13}CO/^{12}CO$. Indeed it is strikingly apparent that for at least one important element, hydrogen, isotopic fractionation is very important in molecular clouds. The interstellar D/H ratio has been measured to be $\sim 10^{-5}$ by means of ultraviolet spectrometers on the Copernicus satellite. On the other hand, of the seven deuterated molecules that have been positively or possibly identified in molecular clouds (HD, DCN, DCO^+, DNC and deuterated water, ammonia, and methylamine), none have yielded abundances, in a ratio to the corresponding non-deuterated molecule, within an order of magnitude of 10^{-5}. HD, for example, also observed in the ultraviolet with the Copernicus satellite[18], is $\sim 10^6$ times less abundant than H_2, whereas the other six deuterated molecules, all seen by means of their radio spectra, seem typically to be only 10^2 times less abundant than their non-deuterated counterparts.

Despite these obvious fractionation effects, it seems that it may be possible to say something about the D/H ratio as a function of position in our Galaxy. Near the galactic centre DCN seems to be underabundant relative to its abundance in the vicinity of the Sun. This has been interpreted[19] to mean that deuterium itself is underabundant near the galactic centre where most of the observed gas has been processed through stars, in agreement with earlier notions from stellar evolution theory that nuclear burning in stars destroys D rather than produces it. If so, one is tempted to attribute the creation of the interstellar deuterium to the Big Bang explosion. In the simple case of a conventional general relativistic cosmology, a D/H ratio $\gtrsim 10^{-5}$ implies that our expanding Universe is open and will continue to expand forever.

Birth and death of stars

Historically, the stars have not been objects of affection for radio astronomers. Because of their poor angular resolution, radio telescopes are ill-suited to the study of minute objects such as stars, particularly since most stars do not emit much radio energy. Molecular radio astronomy is at a further disadvantage in that bright massive main-sequence stars that are burning hydrogen to helium in their interiors emit so much ultraviolet radiation that all nearby molecules are rapidly destroyed by photo-dissociation. During the past few years, however, it has become evident that the regions in our galaxy where interstellar molecules are observed are usually associated with either the birth or the death of a star or star cluster[20].

The most obvious signposts for star formation in our Galaxy are the hot, bright, blue O and B type stars that are 10^4–10^5 times as luminous as our sun and which are often surrounded by glowing clouds of ionised gas called H II regions. The Orion Nebula is the most famous H II region in the sky and is visible to the naked eye as the middle 'star' in the sword of Orion, the Hunter. Often associated with these O stars and H II regions are giant molecular clouds, which appear to be fragmented on at least three mass scales: 10^5, 10^3, and 10 times the mass of our Sun ($M_\odot$). O and B type stars are often found in associations composed of subgroups separated by 30–60 light years and strung out along the galactic plane[21]. It may be possible to identify strings of giant $10^5 M_\odot$ molecular clouds as the precursors of these OB sub-groups[22]. Each $10^5 M_\odot$ cloud in turn seems to fragment into $10^3 M_\odot$ pieces separated by distances $\sim$3 light years, and which may be precursors of galactic star clusters, such as the Trapezium, which is located at the centre of the Orion Nebula. Near the Orion Nebula, for example, there is a giant molecular cloud that appears to have fragmented into half a dozen or more pieces[23]. The fragmentation process may take millions of years.

The $10^3 M_\odot$ pieces fragment further into stars, many of which are seen as infrared continuum sources buried in the molecular clouds. Often associated with the infrared sources are bright OH (hydroxyl) and water masers, which come from regions comparable with or somewhat larger than the size of our Solar System. Perhaps, if we are both clever and lucky, we shall someday be able to use these masers as a tool for understanding the final stages in the formation of stars and associated planetary systems.

The superficial picture of star formation that we have pieced together above is still riddled with fundamental uncertainties. That is, we still have no clear understanding of motions in molecular clouds and, unlike the main-sequence phase in a star's life, motion is what star formation is all about. The relative importance of magnetic, rotational, gravitational and turbulent motions and forces in molecular clouds is still a subject of hot controversy. A few years ago it was suggested that the broad CO lines observed in molecular clouds could be best explained by free-fall collapse with velocity proportional to radius of large sections of the clouds[24,25]. But there are problems with such models[26,27], including, for example, excessive star formation rates. The recent observation[28] of self-reversed CO profiles in some molecular clouds suggest that, at least in these clouds, collapse is not very fast or v is not proportioned to r, or both. Although interpretation of these observations is still ambiguous[29], certain asymmetries present in the CO profiles suggest collapse velocities that are comparable with turbulent velocities. But other clouds have been seen with the opposite asymmetries in the CO profiles, thus suggestive of expansion rather than collapse.

If supersonic turbulence is present in molecular clouds, it will die out quickly unless it is regenerated or the clouds are very clumpy. The degree of clumpiness on size scales less than a few tenths of a light year is under investigation[30,31]. The part, if any, played by magnetic fields is still unclear. Some clever new ideas and/or observations are required if we are to improve our incomplete understanding of star formation.

The death of stars is a somewhat better understood process than their birth. This is because evolved stars, such as red giants, and dying stars, such as planetary nebulae white dwarfs and supernovae, have been studied optically for many years. Except for the white dwarfs, each of these types of star is known to be losing significant mass into interstellar space. Red giants and planetary nebulae are common objects and it is believed that most stars with masses greater than the mass of our Sun pass through both of these stages of evolution. Until very recently, however, it was not clear that anyone had actually seen stars that were evolving between the red giant phase and the planetary nebula phase.

An infrared survey from rockets[32] has been followed by ground based infrared[33–38] and radio molecular[39–41] observations of some of the very cool stars seen from the rockets. It now seems that the progenitors of planetary nebulae may be observable as very cool, extreme cases of red giant stars. The central stars in these progenitors are enshrouded in a cool circumstellar envelope composed primarily of molecules and dust particles. The presence of the cool dust is deduced from infrared 'excesses', often observed at wavelengths of 3–20 μm. The cool dust absorbs the visible and near infrared light emitted by the underlying star and by hotter dust and reradiates it at longer infrared wavelengths.

The gaseous molecular envelope is best studied by means of radio spectroscopy. Envelopes in red giant stars with more oxygen than carbon ('oxygen-rich') were first detected[42] eight years ago by means of OH maser radiation that they emit. Later, both water[43] and silcon monoxide[44] masers have been observed from many of these oxygen-rich stars. The apparent sizes of the OH and H_2O emission regions have been measured by trans-continental and inter-continental radio interferometers to be extremely small (of the order of the size of our Solar System). Because the strongest SiO masers are due to transitions between rotational levels in the first and second excited vibrational states which require energies of thousands of degrees for excitation, there is good reason to suspect that the SiO masers will come from even smaller regions than the OH and H_2O masers. (Because SiO is a stable molecule, it is not unreasonable that it might exist near or even on the stellar surface.)

Because we now know of three different molecules that produce high gain maser radiation in oxygen-rich stars and because the maser levels have different excitation energies, a wide range of conditions in the outer stellar atmospheres and circumstellar envelopes may be investigated with high spatial resolution. With such data in conjunction with the infrared observations we may hope to eventually gain a detailed understanding of mass loss mechanisms and of the physical conditions around evolved oxygen-rich stars[45]. In particular, it is already known that the OH and H_2O maser outputs follow intensity variations in the near infrared flux so that the masers are probably 'pumped' by near and/or far infrared radiation emitted by the star.

The other kind of evolved red giant stars, those with more carbon than oxygen in their outer layers, are rarer than the oxygen-rich stars discussed above. Recent radio observations[41] suggest that many of these carbon-rich stars may be losing mass at a rate comparable with the mass loss rates for planetary nebulae and significantly greater than the rate of mass loss from most oxygen-rich stars[46]. Unfortunately, largely by a quirk of fate, it is not possible to measure the carbon-to-oxygen ratio in planetary nebulae by optical techniques. An interesting problem for future investigation will therefore be to determine if most or only a relatively small fraction of planetaries pass through a carbon star stage.

Comparison of the lifetimes, compositions, distribution, kinematics and masses of planetary nebulae and carbon-rich and oxygen-rich infrared stars should lead to a clearer understanding of the physical mechanism responsible for the ejection of a planetary nebula envelope. It is also possible that the oxygen- and carbon-rich stars form two successive stages in an evolutionary sequence leading to planetary nebulae. It is already known that the distribution and kinematics of the oxygen-rich, variable stars are similar to those of the planetary nebulae. It is therefore conceivable that red giant stars first shed their oxygen-rich outer envelopes at a relatively leisurely pace and thereby reveal a carbon-rich interior region which is then shed more rapidly to form a planetary nebula. Whether this scenario is representative for most or only a few stars awaits further observational tests.

Galactic and extragalactic structure

Because the Milky Way contains an appreciable amount of dust that scatters and absorbs light waves from distant stars, it was not until the advent of spectral line radio astronomy in the 1950s that a complete map of the Milky Way could be constructed. The maps were of the intensity of 21-cm wavelength radio waves emitted by neutral atomic hydrogen located throughout the Galaxy. In conjunction with a simple model for the revolution of mass about the galactic centre, it was possible to plot the distribution of hydrogen atoms in the Galaxy. It was assumed that this map would also represent the distribution of other young constituents in the Galaxy (by 'young' we mean objects such as bright massive stars and their remnants (for example pulsars), which are believed to have formed out of the gas within the past few times 10×10^6 yr). Some astronomers were therefore surprised when the first large scale maps[47–49] of the very abundant interstellar carbon monoxide molecules showed a distribution that is very different from the distribution of hydrogen atoms. The molecular maps indicate that the CO clouds are concentrated near the centre of our pancake-shaped Galaxy, as well as in a ring lying between 4 and 8 kiloparsecs (kpc) from the centre. Very few molecular clouds are located at or beyond the circle of radius 10 kpc that our Solar System traverses as it orbits around the galactic centre. The atomic maps, on the other hand, indicate a fairly uniform density of hydrogen between 4 and 14 kpc from the galactic centre. Therefore, the bulk of the atomic gas lies outside of the solar circle. Since the CO is believed to trace out the distribution of the (unobservable) H_2 molecule, the inescapable conclusion is that atomic (H) and molecular (H_2) clouds in our Galaxy have very different distributions.

The explanation for this difference is not yet certain, but it probably has something to do with the large scale spiral structure of the Galaxy. That is, the 'typical' low density atomic hydrogen cloud, or group of clouds, is not sufficiently massive to become gravitationally unstable and collapse to form denser clouds where H_2 molecules can be formed and protected. Help is needed and such help is probably provided by a spiral density wave that produces shock fronts and compresses the atomic clouds in the inner, but not the outer parts of the Galaxy[47]. Some of the compressed clouds or groups of them become gravitationally unstable and can collapse. (The collapse process might also involve the galactic magnetic fields.) Because current star formation is believed[20] to be more closely tied to molecular, rather than atomic clouds, it is not surprising that the best available pictures of the distribution of massive young stars[50] (indirectly visible at great distances from the sun by the radio waves emitted in the extensive hot plasmas that surround them) and supernova remnants[51] agree much better with the CO maps than with the 21-cm hydrogen maps.

Maps[52] of the galactic γ-ray (energies $\gtrsim 100$ MeV) distribution also show a remarkable resemblance[53] to the CO maps. Because the most likely γ-ray production mechanism is interaction of cosmic ray nucleons with interstellar gas nuclei, the γ-ray maps trace out a product of the densities of these two galactic constituents. The data suggest[53,54] that the cosmic ray intensities are somewhat enhanced in the general vicinity of the molecular clouds and the supernova remnants and that cosmic rays, at least those of energies 1–10 GeV, originate in the Galaxy (as opposed to outside it).

Because of the widespread distribution of CO in the Milky Way, it has been expected that the CO rotational spectrum would also be observed from other galaxies. Recently, however, radio astronomers finally detected extragalactic CO near the centre of one active irregular, four active spiral galaxies[55], and in the Large Magellanic Cloud[56], a very nearby irregular galaxy, easily visible with the naked eye from the Southern hemisphere. By 'active' we mean that the galactic central regions emit strong infrared and radio frequency continuum radiation and optical emission lines, as well as showing evidence for non-circular motions and mass ejection. These are also characteristics of the centre of the Milky Way, albeit on a smaller scale. Because the single largest concentration of molecular clouds in our Galaxy is located near its centre, it is not surprising that the nuclei also contain the most impressive concentrations of molecules in the active galaxies. In all of these galaxies, including our own, the molecular clouds and energetic phenomena are probably associated with star formation and death. Gravitational forces tend to enhance the nuclear densities, which result in massive molecular clouds and relatively rapid rates of formation of stars which excite the interior regions and might lead to violent (explosive) events such as supernovae. With somewhat more sensitive receivers, millimetre wavelength interferometers, and larger telescopes it should be possible to greatly expand our knowledge of the distribution of extragalactic molecules. Higher angular resolution, for example, would enable radio astronomers to map the (spiral) structure of other galaxies and to compare the molecular distribution with the distribution of dust, atomic gas, emission nebulae, and synchrotron radiation. Better sensitivity will allow study of the less abundant isotopes of CO and other molecules which in turn will help us to understand the chemical history of these galaxies.

Summary

The study of interstellar molecules during the past decade has been remarkably productive. Future prospects look equally bright. New large telescopes and interferometers sensitive to millimetre wavelength radiation will permit substantially more detailed study of molecules in regions of stellar birth and death in the Milky Way and external galaxies. New instrumental techniques have already pushed the short wavelength frontier to sub-millimetre wavelengths (the observation[57] of the $J=3\rightarrow2$ transition of CO on the 200-inch Hale telescope). Portions of the millimetre and sub-millimetre spectrum, not accessible from the ground because of atmospheric absorption, will be observable from aircraft, balloons and satellites. Initial steps in this direction have been taken[58] with a 183 GHz radiometer flown on the G. P. Kuiper Airborne Observatory.

Perhaps the most fertile, as yet largely unexplored, area of the spectrum is the infrared, where high resolution spectroscopy is still in its infancy. H_2 rotation–vibration transitions near 2-μm wavelengths have recently been detected[59] for the first time in interstellar space towards the Orion Nebula and a planetary nebula.

I thank Dr F. J. Kerr and Mr R. Sinha for reading and commenting on an earlier version of this manuscript. The preparation of this review was supported in part by grants from the US National Science Foundation and the Alfred P. Sloan Foundation.

β-Sheet topology and the relatedness of proteins

Jane S. Richardson

Department of Anatomy, Duke University, Durham, North Carolina 27710

The topological connectivities of β-pleated sheets in the known protein structures are systematically surveyed for regularly occurring features. The many empirical restrictions found and the distribution of actually occurring topologies among the hypothetically possible ones suggest that striking topological similarities between different proteins can readily happen by chance.

β-PLEATED sheets are major features in about 80% of the globular proteins of known three-dimensional structure, and β sheets inherently require the close interaction of regions separated in the amino acid sequence. An understanding of β sheets is therefore central to an understanding of the organisation and folding of proteins, and will probably be essential in any successful method of predicting three-dimensional structure from amino acid sequence. A number of particular regularities have been noted in β structure[1–4], but there has been no systematic search for such features.

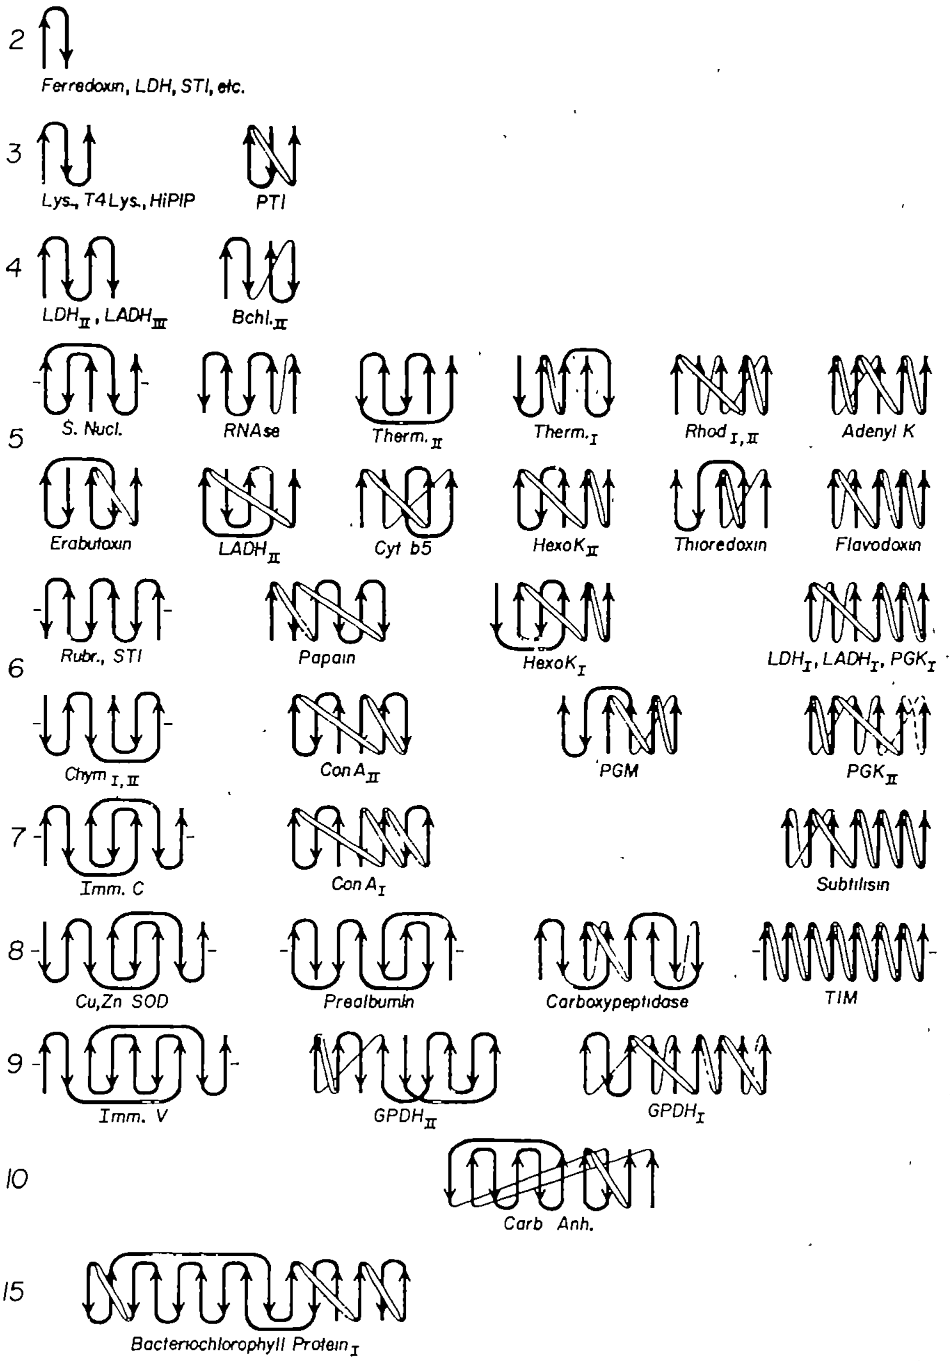

Fig. 1 Schematic diagrams for all the topologically-distinct β-pleated sheets found in proteins of known three-dimensional structure. Arrows indicate the strands of the β sheet, considered to be in the plane of the paper; crossover connections shown wide are above the sheet and thin ones are below it. Only topological connectivity is represented, with no attempt to indicate the length or conformation of the connections. The β sheets are sorted from top to bottom by number of strands, and from left to right according to their percentage of antiparallel as against parallel β structure. In cases of proteins with more than one β sheet, roman numeral subscripts are added. Those β sheets which can be considered to form cylindrical barrels are flanked by hyphens and are shown as viewed from the outside. Abbreviations and literature references for the 33 proteins included (in decreasing order of β-sheet size) are as follows: bacteriochlorophyll protein (Bchl)[8], carbonic anhydrase C (Carb. anh.)[9], glyceraldehyde phosphate dehydrogenase (GPDH)[10], immunoglobulin variable (Imm. V) and immunoglobulin constant (Imm. C) domains[11], Cu,Zn superoxide dismutase (Cu,Zn SOD)[12], prealbumin[13], carboxypeptidase A[14], triose phosphate isomerase (TIM)[15], concanavalin A (Con A)[16], subtilisin[17], chymotrypsin (Chym.)[18], phosphoglycerate mutase (PGM)[19], phosphoglycerate kinase (PGK)[20], rubredoxin (Rubr.)[21], soybean trypsin inhibitor (STI)[22], papain[23], hexokinase (HexoK)[24], lactate dehydrogenase (LDH)[25], liver alcohol dehydrogenase (LADH)[26], erabutoxin[27], cytochrome b5 (Cyt. b5)[28], thioredoxin[29], flavodoxin[30], staphylococcal nuclease (S. nucl.)[31], pancreatic ribonuclease (RNAse)[32], thermolysin (Therm.)[33], rhodanese or thiosulphate sulphurtransferase (Rhod.)[34], adenyl kinase (Adenyl K)[35], egg white lysozyme (Lys.)[36], T4 phage lysozyme (T4 Lys.)[37], high-potential iron protein (HiPIP)[38], pancreatic trypsin inhibitor (PTI)[39]; ferredoxin[40].

Similarity of the topological connectivity of β-sheet strands has been central to consideration of the possible evolutionary relationship between distantly similar proteins[1-7], but it has been very difficult to evaluate the significance of such topological similarities. Here I introduce both a graphical and a notational convention for representing the topological connectivity of β sheets, and use this highly simplified representation to systematically survey the known β sheets for regular patterns. Possible implications for the folding and for the evolutionary relatedness of proteins are pointed out.

The possible backbone connections between β strands fall into two general categories: 'hairpin' connections in which the backbone chain re-enters the same end of the β sheet it left, and 'crossover' connections in which the chain loops around to re-enter the sheet on the opposite end (illustrated in Fig. 1 of ref. 2). Starting from the N-terminal strand, each connection is named by how many strands it moves over in the sheet and in which direction, with an 'x' added for crossover connections. Thus a '$+1$' is a hairpin and a '$+1x$' is a crossover connection between nearest-neighbour strands; a '$+2$' is a hairpin and a '$+2x$' is a crossover connection that skips past one intervening strand in the sheet, and so on. As an example, the five-stranded β sheet of thioredoxin (see Fig. 1) can be described as either $-2x, +1x, -2, -1$ or as $+2x, -1x, +2, +1$ (absolute value of the signs is not meaningful, since the diagram could be turned upside down).

Figure 1 shows simplified topological diagrams for the 37 topologically distinct β-sheet structures found in proteins of known three-dimensional structure. Assignment of these β-sheet topologies was made from examination of stereo drawings, hydrogen-bonding diagrams, and published descriptions of the structures. In some cases a decision must be made about inclusion or omission of a particular extended strand: very short strands which turn abruptly away after making one hydrogen bond were generally omitted if they were at an edge of the sheet, while long extended strands which stay close to a neighbouring strand are generally included even if they are not known to form hydrogen bonds (for example, a fifth parallel strand in rhodanese). Also, each continuous stretch of extended chain is treated as a single β strand; this is the usual convention but differs, for example, from the usage in ref. 4. All of these β sheets have the usual twist[1], although that is not shown in these schematic diagrams. All consideration of length and conformation in the connecting backbone chains is omitted, in order to concentrate on the purely topological features. Figure 1 thus summarises the empirical data base from which all of the following conclusions are drawn.

Handedness of crossover connections

All crossover connections are right-handed (except for one, in subtilisin). That is, in Fig. 1, crossover connections above the β sheet all slant down to the right, and crossover connections below the sheet all slant down to the left. This handedness phenomenon is discussed in detail elsewhere[2].

Parallel β structure only in large, protected sheets

No parallel β structure occurs in sheets of less than five total strands. This suggests that considerable cooperativity is necessary to stabilise parallel β structure, whereas antiparallel β structure often occurs as a twisted ribbon of just two strands.

Parallel β sheets and the parallel portions of mixed sheets are always thoroughly buried, with other main chain (often α helices) covering them on both sides. Antiparallel sheets, on the other hand, typically have one side exposed to solvent with only the rather sparse protection of the side chains. This pattern also suggests a lower stability for parallel β structure, since apparently it cannot tolerate solvent access to its hydrogen bonds. The necessity for considerable protein structure on both sides of a parallel β sheet (as well as the need for loops to make the crossover connections) means that parallel sheets occur only in relatively large protein domains. For domains built around a parallel β sheet the average size is 179 residues with a minimum of about 135, whereas for domains built around a large antiparallel sheet the average size is 128 residues and the minimum is 54.

For right-handed crossover connections to shield both sides of a non-cylindrical parallel β sheet, there must be at least one change of direction (change of sign in the written convention). Apparently these direction changes are somewhat unfavourable for parallel sheets, since none of the nine pure parallel β sheets change direction more than once, although for antiparallel and mixed sheets of similiar sizes 11 out of 20 examples change direction two or three times.

	↑↓	Mixed	↑↑	Total
±1	57	48		105
±1x		12	32	44
±2		9		9
±2x	7	8	7	22
±3	8	4		12
±3x		7	5	12
±4		2		2
±4x	4			4
±5		3		3
±7		1		1
±7x		1		1
±8x		1		1

Fig. 2 Occurrence frequencies of each connection type in the known β sheets. The number of occurrences in pure antiparallel, in mixed, and in pure parallel β sheets are tabulated separately, and are totalled for all β sheets of 5 or more strands.

Connection type frequencies

Figure 2 gives the number of occurrences of each connection type. Of the connections that occur, 70% are either ±1 or ±1x. This fact alone is sufficient to make some β-sheet topologies much more favourable than others, as has previously been pointed out[6].

Asymmetries of chain direction

For almost all local (2 or 3 strand) topological features, occurrence frequencies seem to be indifferent to backbone chain direction. One exception is that the N-terminal strand is somewhat more likely than the C-terminal strand to be in the middle of the β sheet: 15 N-terminal strands are at an edge, 4 are in by one strand, and 14 are in by more than one strand; while 22 C-terminal strands are at an edge, 7 are in by one strand, and only 4 are in by more than one strand. This supports the view that there is a tendency for the earliest folding nucleation sites to be near the beginning of the chain.

In general, reversal of chain direction produces a topologically distinct structure (except in occasional symmetrical cases, such as chymotrypsin and the immunoglobulin domains); however, since occurrence frequencies of all the local patterns except the buried N termini are indifferent to chain reversal, the following discussion assumes that a given topology and its reversed version have the same probability of occurrence.

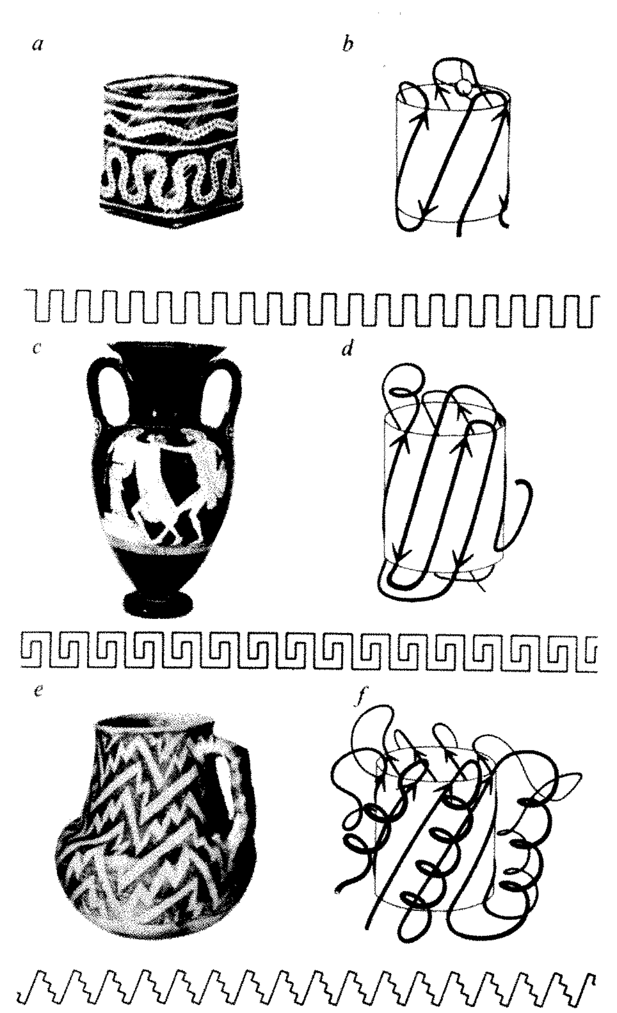

Fig. 3 Comparison of geometric motifs common on Greek and American Indian weaving and pottery with the backbone folding patterns found for cylindrical β-sheet structures in globular proteins. *a*, Indian polychrome cane basket, Louisiana. *b*, Polypeptide backbone of rubredoxin. *c*, Red-figured Greek amphora showing Cassandra and Ajax (about 450 BC). *d*, Polypeptide backbone of prealbumin. *e*, Early Anasazi Indian redware pitcher, New Mexico. *f*, Polypeptide backbone of triose phosphate isomerase. Simplicity of commonest topological patterns

Among locally interconnected 4-strand regions, the only topologies that occur more than 3 times are: $+1,+1,+1$ 16 times; $+3,-1,-1$ 11 times; $+1x,+1x,+1x$ 6 times; and $+1x,+2x,-1x$ 5 times. These frequencies are about what would be expected from the occurrence frequencies of the individual connection types making them up (see Fig. 2), except that $+3,-1,-1$ occurs more often than expected. Perhaps one reason why that pattern is especially favoured is that besides folding up one strand at a time it can also fold by forming a long 2-stranded ribbon which then bends in the middle.

The distinctive topological patterns which are seen in the β-barrel structures are the simple up-and-down 'meander' pattern of $+1,+1,+1$ (as in rubredoxin and soybean trypsin inhibitor); the 'Greek key' pattern of $+3,-1,-1,+3$ or just $+3,-1,-1$ (as in staphylococcal nuclease, chymotrypsin, immunoglobulins, superoxide dismutase and prealbumin); and the strict alternation of parallel β with helix in the 'lightning' pattern of $+1x,+1x,+1x$ (as in triose phosphate isomerase). As shown in Fig. 3, each of these patterns corresponds to a common geometric motif used to decorate weaving and pottery. Besides providing a useful mnemonic for the β-barrel structures, this comparison emphasises the fact that, like good pottery decoration, the topological patterns found in β structure are not haphazard collections of lines but are subject to constraints of simplicity and good design.

For parallel β barrels, since crossover connections must be right-handed and cannot go down the centre of the barrel, a rigorous repetition of $+1x,+1x,+1x$ in the lightning pattern is the only likely topology. Therefore it is to be expected that any parallel β barrels found in the future will very closely resemble triose phosphate isomerase, whether they are related to it or not.

The Greek key topology of $+3,-1,-1,+3$ is symmetrical to chain reversal, but when it occurs on a barrel it has two mirror-image forms, depending on whether the swirl is clockwise or counterclockwise as viewed from the outside of the barrel (see Fig. 3 insert and cover). For all five proteins with Greek key β barrels, the swirl is counterclockwise. This could simply be a strong coincidence; however, it seems likely that the counterclockwise swirl either folds more easily or is a stable structure (the two forms are not exact mirror images, because the β strands always have a right-handed twist and the amino acids are asymmetrical).

Preference for pure over mixed sheets

The ratio of the number of pure parallel or pure antiparallel β sheets to the number of mixed sheets is very much greater than would be expected from a random distribution. In our sample there are 124 antiparallel and 73 parallel strand pairs in the sheets of at least 5 strands. If the parallel and antiparallel probabilities are considered approximately equal and if they were independent from one pair to the next across the β sheet, then there should be approximately 2 pure sheets (one parallel and one antiparallel) for every 14 mixed sheets in 5-stranded cases, and 2 pure for every 30 mixed in 6-stranded cases. Since Fig. 1 contains 12 5-stranded and 8 6-stranded sheets, the expectation would be 2 pure and 18 mixed sheets if the probabilities were independent; in fact there are 12 pure and only 8 mixed sheets out of the 20.

It is easy to understand why the parallel and antiparallel probabilities are not independent from one strand pair to the next: since the ideal conformations for the two types of β structure are slightly different, a strand which has antiparallel hydrogen-bonding on one side is already set up for antiparallel hydrogen bonds on the other side. Indeed, it turns out that 138 strands have the same type of bonding on both sides, while only 33 have opposite bonding types on the two sides.

One interesting result of this strong preference for pure rather than mixed β sheets is that although the current set of known protein structures is beginning to provide a statistically meaningful sample of the pure β sheets (18 with >4 strands), the 14 mixed sheets are actually 15 times sparser sampling out of the possible cases, and therefore very little can yet be said about them.

Absence of knots

There are no knotted topologies within the known β sheets—that is, no backbone β-sheet configurations which, if considered as a rope grasped at N and C termini and pulled out straight, would end up with a knot in the rope. (However, the backbone of carbonic anhydrase C contains a knot involving the first 30 residues (not part of the β structure) and the last 20 residues (which do include a β strand). (Presumably a knot is not impossible if the piece to be tucked through the loop is very close to a chain end.) It has often been pointed out (for example ref. 41) that it would be exceedingly difficult for a protein to fold up into a knotted configuration. This is not a trivial restriction, since a relatively large number of the hypothetically possible topologies are knotted, especially for parallel sheets. The simplest such case is $+2x, -3x, +2x$, —the one knotted topology out of 12 (if left-handed crossover connections are excluded) for a 4-stranded pure parallel sheet. Of the possible topologies, 25% are knotted for a 5-stranded pure parallel sheet, and 45% of the topologies are knotted for a 6-stranded pure parallel sheet.

Adequacy of a simple nomenclature

One set of restrictive conditions can be summarised by saying that it is almost always possible to describe a real β-sheet topology by a list of connection types. Many of theoretically possible arrangements which would violate this restriction simply do not occur: for instance, two long β strands hydrogen bonded to each other as nearest neighbours at one end but hydrogen-bonded to an intervening β strand at the other end.

Ambiguous chain crossings are also extremely rare in real structures (that is, connections which would be topologically different depending on which of two connection chains was on top). There is just one such case involving hairpin connections in $\mathrm{GPDH_{II}}$ (see Fig. 1), and just one such case involving crossover connections, in subtilisin (see Fig. 1). Often one version of a hypothetical ambiguous pair is knotted; the two versions are not counted as separate topologies in this paper.

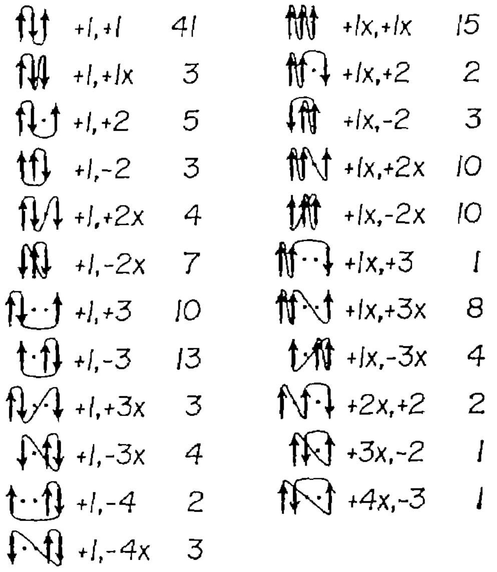

Fig. 4 Occurrence frequencies for consecutive (in the amino acid sequence) pairs of connection types in β sheets of five or more strands. A connection pair and its reversal (for instance, $+1x$, $-2x$, and $-2x$, $+1x$) are tabulated together. Connection pairs that span more than five strands are omitted.

Preference for topologies with many folding pathways

It is possible to assume a hypothetical set of rules for allowable steps of protein folding for β sheets, more or less in agreement with ideas which have often been suggested before[3,42–45]. Assuming that the α helices and β strands are already present at least statistically, let us say that each succeeding step in any possible folding pathway for a β sheet must consist of either (1) forming a ± 1 or $\pm 1x$ connection between two β strands adjacent in sequence, or (2) taking either a β strand or a prefolded unit and laying it down next to a prefolded part of the sheet with which it is also contiguous in sequence. Many hypothetical topologies which do not occur are unfoldable by this definition, including all the knotted ones. But the occurring β sheet topologies typically have a large number of such possible folding pathways (the notable exceptions are subtilisin, with no such pathways because the left-handed $+1x$ lies outside of the $-2x$, and cytochrome b5, with only one). Especially for cases with 10 or 20 potential folding pathways it seems unlikely that one is so much more favourable that it effectively dominates all the others. Instead, it may be that one reason that these structures are favourable is because they can fold correctly by many alternative pathways and therefore tend to fold rapidly and reliably. The idea that some broad features of protein structure are determined by essentially kinetic factors during folding (such as the dominance of near-neighbour strand interactions) is not incompatible with the requirement that the stable native conformation of a protein should be in the global free energy minimum. During its evolution, once a protein finds a reasonably stable, kinetically accessible, minimum energy conformation, it is then subject to natural selection for stability. Selection will dig that particular local energy minimum as deep as possible by adjusting the amino acid sequence to approach optimal fit for the native conformation, and at the same time probably will raise all the other local energy minima whose stability is not being selected for. The result is very likely to be a genuine global energy minimum, in spite of the influence of kinetic requirements.

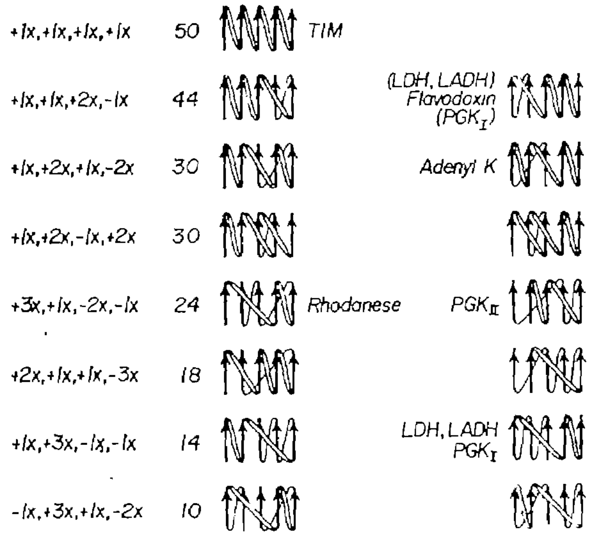

Fig. 5 The most probable topologies for 5-stranded pure parallel β sheets. The first column lists the sequence of connection types. Numbers in the second column are normalised pseudo-probabilities obtained by multiplying occurrence frequencies of the three pairs of connection pairs as described in the text. The diagrams in the last column are obtained by reversal of the backbone chain direction. Next to each diagram are listed all proteins which contain that topology as a contiguous unit (both in sequence and within the β sheet), the protein is in parentheses if a single strand at one end of either the sequence or the sheet was ignored to make the 5 strands contiguous See Fig. 1 legend for abbreviations.

Probability ordering for β topologies and implications for evolutionary relatedness

Figure 4 gives the occurrence frequencies for various consecutive pairs of connection types. These pair frequencies can be used to generate pseudoprobabilities which give a relative ordering among possible β-sheet topologies.

As an example, consider the pure parallel and the pure antiparallel cases, for 5-stranded β sheets. With left-handed crossover connections eliminated (see above), parallel and antiparallel cases each have $n!\ /2 = 60$ possible topologies, consisting of 32 basic patterns and 28 others obtained by reversal of chain direction (4 of the topologies are symmetrical to chain reversal). Each 5-stranded topology contains 4 connections and 3 connection pairs. Its pseudoprobability is defined as the number obtained by multiplying together the occurrence frequencies of its three connection pairs (from Fig. 4, using a frequency of 1 if the pair did not occur in the data base), dividing by 2 for the symmetrical cases, and then dividing by a factor of 34 which normalises the +1,+1,+1,+1 case to 1,000.

Figures 5 and 6 show all pure parallel and all pure antiparallel 5-stranded topologies that have pseudoprobabilities greater than 8. The data sample is large enough (155 connection pairs) so that the pseudoprobabilities respond primarily to the overall connection pair frequencies and are only slightly affected by whether or not the exact 5-stranded topology in question occurs in the data base. The pseudoprobabilities could be further improved by inclusion of factors disfavouring knots, ambiguous chain crossings and buried C termini (see above). Also, for purposes that did not need to consider topologies embedded within larger sheets, it would be useful to include the probability of each connection type being the first or the last. But, the single simple criterion used in Figs 5 and 6 succeeds in including all occurring 5-stranded topologies on a rather short list, and the occurring topologies are a fairly dense sample of these 'most favourable' cases.

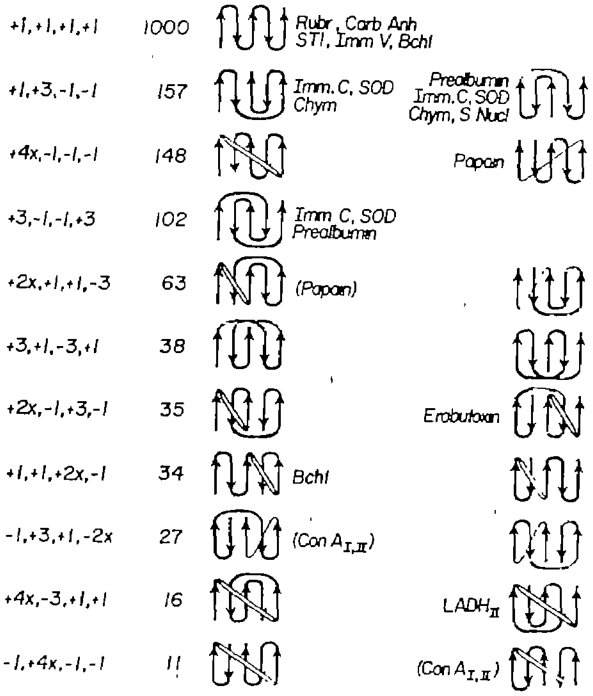

Fig. 6 The most probable topologies for 5-stranded pure antiparallel β sheets. All pure five-stranded topologies which occur as contiguous units in one of the known β sheets are included on the lists of Figs 5 and 6, except for the case of subtilisin, which would match the adenyl kinase entry if it did not have a left-handed crossover connection.

From the overall distribution of examples seen in Figs 5 and 6, it can be concluded that many of the protein pairs which have identical or closely similar β-sheet topologies merely represent coincidentally close choices among the rather few highly probable topologies. There must be examples among such proteins which resemble each other because of a true evolutionary relationship; however, topological similarity of their β structures provides only a very weak argument for such evolutionary relationship, although it is probably a necessary condition. It is suggestive that fully 75% of the pure β sheets are topologically similar to some other one, whereas among the mixed β sheets, for which the current sampling is 15 times sparser (see above), the only topologically similar pair are the two halves of hexokinase. At one extreme, evolutionary relationships almost certainly underlie the similarity of the nucleotide-binding domains of LDH and LADH, and the internal duplications of structure in rhodanese and in the immunoglobulins. At the other extreme, there are almost certainly not evolutionary relationships underlying the topological similarity of the two interdigitated β sheets in con A or underlying the topological similarity of proteins whose overall structural organisation is as different as, for instance, staphylococcal nuclease and Cu,Zn superoxide dismutase. The many cases intermediate between these extremes must each be decided on the basis of other evidence besides topology, but it seems likely from overall statistics that the bulk of them are coincidences produced by the fact that the number of highly favourable chain folding patterns is actually quite limited.

Nerve growth factor-induced increase in electrical excitability and acetylcholine sensitivity of a rat pheochromocytoma cell line

Marc A. Dichter & Arthur S. Tischler

Department of Neurology and Pathology, Harvard Medical School and Beth Israel Hospital, Boston, Massachusetts 02215

Lloyd A. Greene

Department of Neuropathology, Harvard Medical School and Department of Neuroscience, Children's Hospital Medical Center, Boston, Massachusetts 02215

A cloned line of rat pheochromocytoma cells (PC12) which responds to nerve growth factor (NGF) by cessation of division and extension of neurone-like processes, is shown to develop electrical excitability and greatly increased acetylcholine sensitivity in the presence of NGF. This implies that NGF influences the physiological differentiation of certain neural crest derivatives.

LITTLE is known about the mechanisms which regulate the differentiation of neuroblasts into mature neurones. Cell cultures of normal or neoplastic origin have become increasingly useful model systems with which to study this otherwise difficult problem[1]. Recently a clonal cell line of rat pheochromocytoma cells (named PC12) was established which undergoes neurone-like morphologic differentiation in the presence of nerve growth factor (NGF) (ref. 2). NGF is a well characterised protein which stimulates neurite outgrowth from sympathetic neurones and which is thought to have an important role in their normal growth and development[3]. After several days in the presence of 10^{-10} M NGF, PC12 cells cease to divide and extend long neurite-like processes. In common with sympathetic neurones, PC12 cells (both NGF-treated and -untreated) also synthesise, store, take up, and release catecholamines[2,4,5]. Such findings suggest that in the presence of NGF, PC12 pheochromocytoma cells differentiate into sympathetic-like neurones.

Among the most characteristic properties of differentiated nerve cells are their electrical excitability and sensitivity to neurotransmitters. In this study, we have therefore chosen to establish whether PC12 cells would generate all-or-nothing actions potentials, if they would respond to acetylcholine (ACh) and if these properties were affected by NGF.

PC12 cells were grown in 35-mm collagen-coated Falcon plastic tissue culture dishes as previously described[2]. 2.5 S NGF (ref. 6) at 50 ng ml^{-1} was added to some cultures. The cells grown without NGF remained relatively spherical (between 6–14 µm in diameter) and did not extend processes. Cells grown in the presence of NGF for longer than 1–2 weeks were, on the average, slightly larger (10–15 µm in diameter) and most cells had one or more long processes. Physiological experiments were performed at 35–37 °C in medium containing 6 mM glucose, 145 mM Na, 3 mM K, 1.8 mM Ca, 1.0 mM Mg, 153 mM Cl buffered by 2.5 mM phosphate or 2.5 mM Tris to *p*H 7.4. The cultures were placed on the stage of an inverted phase contrast microscope and the cells were impaled under direct vision with microelectrodes containing 3.5 M potassium acetate (R = 40–100 MΩ) (ref. 7). The cells were stimulated with intracellular depolarising pulses of 50-ms duration passed through the recording electrode using a modified Wheatstone bridge. In many cases, in order to increase activation of spike generating mechanisms, the cells were hyperpolarised by passing negative background current through the microelectrode before depolarising pulses were applied.

Since PC12 cells are small and therefore subject to injury with the microelectrode, several criteria were used to control for this parameter when comparing spike generative capacity and ACh sensitivity of cells cultured in different conditions. First, recordings were included in our results only if the cell maintained a resting potential of −20 mV or greater. This excluded severely damaged cells. Second, the mean resting potential of each group of cells was determined. While such measurements do not reflect the absolute resting potentials of the unimpaled cells, they do provide a means of comparing the extent of cell damage. Finally, in many cases, comparisons were made with cultures studied on the same day and with the same set of microelectrodes.

Electrical excitability

In more than one hundred impaled PC12 cells with resting potentials greater than −20 mV, from eight different cultures, no cells showed action potentials (Fig. 1*a* and Table 1). This included 58 cells with membrane potentials (V_m) greater than −30 mV and 19 cells with V_m greater than −40 mV. In all cases, the cells were hyperpolarised to between −70 and −100 mV in order to maximally activate any possible spike-generating mechanism present. In two cells, after background hyperpolarisation, depolarising pulses produced small regenerative responses (<10 mV) which could just be distinguished from the delayed rectification which was often present.

In some experiments, more calcium (5.4–10.8 mM) was added to the medium to act as a membrane stabiliser and to enhance any Ca-dependent regenerative responses. Action potentials were not detected in 18 impaled cells (including 9 cells with $V_m \geqslant -30$ mV and 5 with $V_m \geqslant -40$ mV) in these conditions.

As noted above, delayed rectification responses were frequently observed (Fig. 1*a*) indicating that the mechanism controlling the delayed increase in K conductance of action potentials is present in these cells. Previous experiments have suggested that PC12 cells not treated with NGF also possess at

Table 1 Electrical excitability of PC12 cells grown in different conditions

Growth condition	Cell division	Process	Action potentials*	Mean V_m
NGF-untreated	+	−	0/111	31±1
NGF-treated (>2 weeks)	−	++	29/42	33±2
Ara-C (0.25–3 µM)	−	−	11/91	38±1
BUdR (3 µM)	−	−	0/15	35±2
Ara-C+NGF (>2 weeks)	−	++	49/65	44±1

*Numbers indicate cells with action potentials per total cells sampled with V_m equal to or larger than −20 mV.

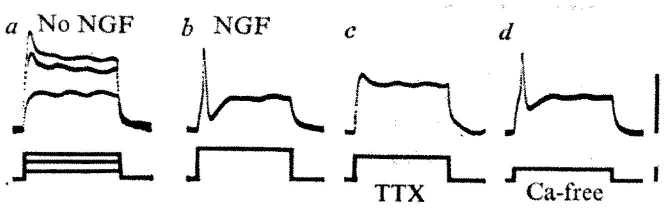

Fig. 1 Electrophysiological responses of PC12 cells. *a*, PC12 cell not treated with NGF. Three superimposed intracellular depolarising pulses (voltage trace above; applied current below) do not evoke a regenerative response. Delayed rectification is seen in the two larger responses ($V_m \simeq -62$ mV*). *b–d*, PC12 cells treated with NGF for more than 2 weeks. *b*, Depolarising pulse evokes action potential in PC12 cell bathed in control medium ($V_m \simeq -58$ mV*). *c*, Depolarising pulse fails to evoke regenerative response in another PC12 cell in presence of 3×10^{-7} M TTX. ($V_m \simeq -54$ mV*). *d*, PC12 cell bathed in Ca-free medium; action potential similar to that seen in *b*. ($V_m \simeq -70$ mV*). Calibration is 50 mV, 1 nA and depolarising pulse is 50 ms. (*, Indicates approximate V_m with background hyperpolarisation).

least some Na action potential ionophores, since veratridine, an alkaloid which specifically activates such sites[8], stimulates release of endogenous catecholamine stores[4]. The inexcitability of untreated PC12 cells could derive from too low a density of such ionophores or from the absence of another component of the action potential generating mechanism or for some other reason.

In PC12 cultures maintained in the presence of NGF for more than 2 weeks, most impaled cells demonstrated all-or-nothing action potentials when depolarised by passing current through the microelectrode (Fig. 1*b* and Table 1). Most often the cells required some background hyperpolarisation to between −50 and −100 mV before the depolarising pulse could elicit an action potential. Resting membrane potentials varied between −20 and −70 mV. In two experiments combined, 22 of 25 consecutively impaled cells showed active responses. In other experiments, presumably because of injury, active responses were found in only 50–80% of penetrated cells. The action potential morphology exhibited by these cells was varied but no cells showed prolonged plateaus, as may be seen in some murine neuroblastoma cells[9]. It could not be determined how much of this variability was attributable to differences in the population or was a function of impalement injury.

Most of the cells in the NGF-treated cultures had long (>100 μm) processes and thus it was possible that action potential generation was directly related to neurite outgrowth. In order to test this, those few cells in NGF-treated cultures which lacked visible processes were impaled. Such cells were still capable of generating action potentials. In another experiment, cells were grown in NGF for 3 weeks and then detached from the culture dish and subcultured into new media with NGF. As a result of this treatment, the cells lost their processes, mainly by mechanical shearing. Within 24 h, the process-less cells had settled on the dish and only a few began to extend short processes. Despite the lack of extensive process formation, at least 60% of the cells were electrically excitable. Both of these experiments indicate that process outgrowth, *per se*, is not responsible or necessary for the development of the action potential mechanism.

The action potentials in the PC12 cells were readily abolished by tetrodotoxin (3×10^{-7} M), an agent known to block Na-action potentials (Fig. 1*c*). In one experiment, action potentials were elicited from 11 of 12 impaled cells in control medium (mean $V_m = -27$ mV), none of 15 cells in TTX-containing medium (mean $V_m = -30$ mV), and 7 of 14 cells in control medium after washout of TTX (mean $V_m = -27$ mV). There were no residual regenerative potentials seen in TTX, as are seen in murine C1300 neuroblastoma cells[9]. Action potentials could also be recorded in PC12 cells in Ca-free solution (Fig. 1*d*). The TTX and Ca-free solution data indicate that the PC12 action potential is generated predominantly by a Na mechanism. Similar results have been found for action potentials of sympathetic neurones[10]. We did not attempt to elicit action potentials in TTX and high Ca, so we cannot exclude a small Ca component to the action potential. Our data indicate that any such component would not contribute a significant amount to the action potential at physiological ionic concentrations.

When NGF is added to PC12 cultures, cell division stops within 4–5 d and the cells begin to put out processes after this time. By approximately 16–18 d most of the cells have processes. We have recorded from cells in sister PC12 cultures after varying days in NGF. Figure 2 shows the percentage of electrically excitable cells in cultures treated with NGF for up to 3 weeks. Because of injury to many cells, each point may be an underestimate, but there is no indication on the basis of the mean resting potentials that NGF protected the cells from impalement injury. The time course for the development of electrical excitability roughly parallels that of the outgrowth of processes[2].

Response to iontophoretically applied acetylcholine

Acetylcholine (ACh) is the depolarising neurotransmitter for both adrenal chromaffin cells and sympathetic ganglion cells[8,10,11]. We tested PC12 cells for responsiveness to ACh in two ways. Microelectrodes filled with 1 M ACh (50–200 MΩ) were positioned just outside the cell to be impaled (within 5 μm). ACh was kept from diffusing out of the electrode by a 5–8 nA negative holding current (although careful testing with sensitive cells revealed that holding currents of 0–2 nA were sufficient for most electrodes used). When a stable impalement was obtained, discrete pulses of ejecting current between 0.5 and 50 ms duration and up to 50 nA were applied to the ACh electrode. The sensitivity of the PC12 cell was then determined as the amount of depolarisation produced by a given current (expressed as mV nC^{-1}). A second test for ACh sensitivity involved switching the holding current from negative (holding) to positive (ejecting; never more than 9 nA) for several seconds. Sensitive cells depolarised within 1–2 s. Less sensitive cells usually responded almost as fast but less intensely.

PC12 cells grown with NGF for more than 2 weeks responded

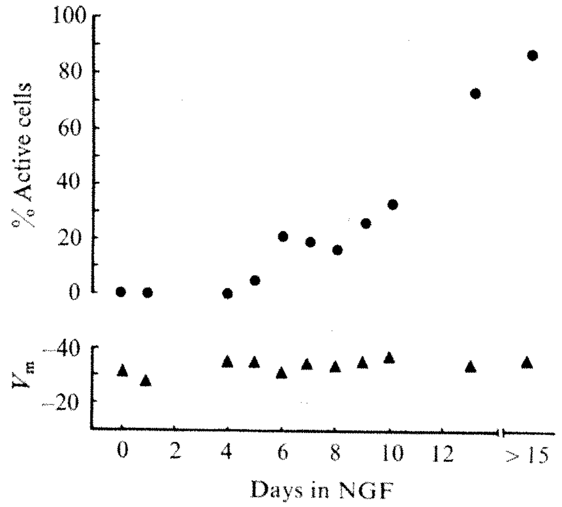

Fig. 2 Percentage of cells in PC12 cultures with action potentials (upper ordinate) and mean membrane potentials (lower ordinate) of these cells (see text) against the no. of days of exposure to NGF. Numbers of impalements for each point were: No NGF, 111; 1 d, 12; 4 d, 22; 5 d, 48; 6 d, 60; 7 d, 77; 8 d, 70; 9 d, 22; 10 d, 18; 13 d, 15; more than 15 d, 42. The standard errors of the mean membrane potentials were between 1 and 3 mV. Note increase in excitability from day 5 to day 13 with no significant change in mean membrane potential.

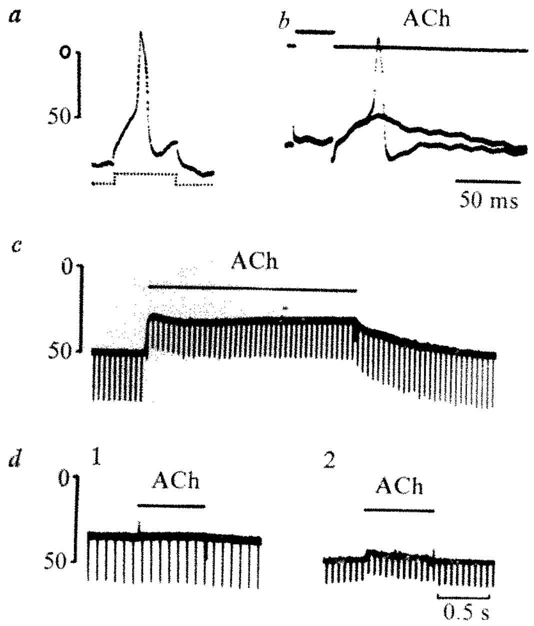

Fig. 3 Response of PC12 cells to iontophoretically applied ACh. *a*, Intracellularly applied depolarising current (dotted line) reaches threshold and triggers an action potential in a NGF-treated PC12 cell. *b*, Two superimposed traces of membrane potential responses to iontophoresis of ACh (14 nA, 30 ms iontophoretic current indicated in top line) on to same cell as in (*a*). Induced depolarisation reached threshold in one trace and triggered an action potential. *c*, Penwriter record of membrane potential of NGF-treated PC12 cell during steady iontophoretic application of ACh ($I = 6.5$ nA). Constant current hyperpolarising pulses were applied to the cell to indicate decrease in input resistance during ACh application. *d*, Penwriter records of ACh responses in two PC12 cells from cultures not treated with NGF. Note no response in (1) ($I = 8.5$ nA) and very small depolarisation in (2) ($I = 6.5$ nA) associated with barely detectable change in input resistance. These records were typical of responses in NGF-treated and non-treated cells. Time calibration in (*d*) applies to *c* and *d*.

to short pulses of current by producing short latency depolarisations which could trigger action potentials (Fig. 3*a*, *b*). Sensitivity was as high as 100 mV nC^{-1}. The ACh response was also associated with an increased membrane conductance (Fig. 3*c*). The ACh-induced depolarisation became larger with background hyperpolarisation and smaller with background depolarisation of the cell. In the above respects, the response resembles the ACh response seen in chromaffin cells[7,11,12] and sympathetic ganglion cells[10]. Prolonged iontophoretic currents produced depolarisations between 4 and 44 mV (mean of 20 cells, 17 mV) which were also associated with an increased membrane conductance. There were very few cells in the NGF-treated cultures which were unresponsive to ACh. No cells produced hyperpolarising responses.

No cells in the NGF-untreated cultures could be depolarised with short pulses of ACh—even with pulses up to 50 nA in intensity and 50 ms in duration and after hyperpolarisation of the cells to between −50 and −80 mV. Sensitivities as low as 1 mV nC^{-1} would have been detectable. But, PC12 cells grown without NGF could be depolarised by prolonged iontophoretic currents of ACh, but to a much lesser extent than the NGF-treated cells (Fig. 3*d*). The maximum response to several seconds of 8 nA current was 6 mV (mean of nine cells, 4 mV).

The responses to short pulses of ACh in the NGF-treated cells was of short latency (< 5 ms). *d*-Tubocurarine at 10^{-5} M added to the perfusing medium abolished all responses to short pulses of iontophoretic current and substantially reduced the ACh response to prolonged currents. These properties suggest that the ACh response was mediated through nicotinic receptors. This would correlate with the demonstration that noradrenaline can be released from PC12 cells by nicotinic agents[5].

Does inhibition of cell division induce differentiation?

The above data indicate that NGF treatment of PC12 cells profoundly affects their electrical excitability and chemosensitivity. One question raised by these results is whether such changes are merely a consequence of the arrest of cell division which takes place in the presence of NGF, or whether they are due to a more specific action of the factor. To test the former possibility, PC12 cells were treated with the anti-mitotic agents cytosine arabinoside (ara-C, 0.5–3 μM) and bromodeoxyuridine (BUdR, 3 μM) for up to several weeks. While both drugs produced a stable population of non-dividing cells, they did not stimulate fibre outgrowth. Physiological experiments revealed that a low proportion (10%) of such cells could generate active responses (Table 1). These responses were, however, much smaller in magnitude than those displayed by the NGF-treated cells. Furthermore, the ACh sensitivity of the division-arrested cells was comparable with non-NGF-treated rather than NGF-treated cells. Interestingly, cells treated with ara-C maintained their ability to respond to NGF. Such cells extended processes and displayed electrical excitability and ACh sensitivity properties comparable with those of NGF-treated control cells (Table 1).

The above findings suggest that the arrest of cell proliferation alone is not sufficient to account for the effects of NGF on the physiological behaviour of PC12 cells. Such changes are likely to be part of the overall constellation of differentiative events which are triggered by the factor.

Comparison with neuroblastoma cells

Another widely used model culture system with which PC12 cells might be compared are murine C1300 neuroblastoma cells. In appropriate conditions, the latter may also exhibit neuronal features, such as neurotransmitter synthesis, ACh sensitivity and electrical excitability[1]. The action potentials of neuroblastoma cells have both Na and Ca components[9]; those of PC12 cells involve predominantly Na. Neuroblastoma cells show hyperpolarising as well as depolarising responses to ACh[1,13] while the ACh responses of PC12 cells are exclusively depolarising. In addition, PC12 cells have been found thus far to differentiate only in response to NGF (ref. 2), while murine C1300 neuroblastoma cells can be induced to stop dividing and differentiate by a number of different agents but not by NGF (ref. 1). In this regard, the PC12 cells may be analogous to human neuroblastoma cells, which have also been shown to extend processes in response to NGF treatment[14–16]. PC12 cells are also analogous to cultured human pheochromocytoma cells which also respond to NGF and are electrically excitable[16,17].

PC12 line as a model system

The morphology and catecholaminergic properties of NGF-treated PC12 cultures have suggested that the overall effect of the factor on such cells is to promote their differentiation into sympathetic-like neurones[2,4,16]. The present findings regarding the emergence of electrical excitability and a high level of ACh sensitivity strongly support this contention.

Pheochromocytoma tumour cells are generally considered to be neoplastic counterparts of normal adrenal medullary chromaffin cells. The NGF-treated PC12 cells, in common with both human pheochromocytomas[17] and normal chromaffin cells[7], can synthesise and store catecholamines, are able to generate action potentials and can exhibit relatively high levels of ACh sensitivity. These properties are also shared with sympathetic neurones. In fact, sympathetic neurones and adrenal chromaffin cells are both of neural crest origin and are both derived from a common stem cell[18]. The low degree of physiological development and the ability to take on neuronal properties suggest that the PC12 cells not treated with NGF may possess the characteristics and pluripotency of a primitive, less differentiated common progenitor. If the analogy of PC12 cells to such a precursor holds, then this, in turn, supports the suggestion[3,19] that NGF, in addition to its documented effects on post-mitotic cells, has a critical role in promoting the development of normal sympathicoblasts into mature, electrically excitable neurones. Thus, the PC12 line may be a unique model system in which to study the differentiation of neuroblasts into neurones as well as for clarifying the role, mechanisms, and consequences of action of NGF on its target cells.

Our results also suggest that the PC12 line should be useful for physiological studies. In particular, it may be feasible to use the PC12 line to obtain biochemical correlates of the development of electrical excitability and chemosensitivity. Seen from a somewhat different orientation, our findings suggest that PC12 cells may be useful to study certain cell–cell interactions. For example, since NGF-treated PC12 cells are highly sensitive to ACh, they should be capable of receiving cholinergic synaptic inputs. Furthermore, not only do PC12 synthesise, store and release catecholamine neurotransmitters, but, like cultured sympathetic neurones[20], they may also synthesise, store and release ACh (ref. 21). Thus, PC12 cells may be capable of forming synapses with a variety of target cells as well as with one another.

We thank Bernard Biales and Mrs M.-N. Chou for technical assistance, and Drs Richard Sidman, Ed Furshpan, Gerald Fischbach and Michael Selzer for reviewing this manuscript. Large number hypothesis and continuous creation cosmologies

Ian W. Roxburgh

Queen Mary College, University of London, Mile End Road, London E1, UK

The large number hypothesis and the condition that general relativity is satisfied in Einstein units, allows a family of cosmological models, two of which are the Dirac model without creation and the more recent Dirac model with multiplicative creation. The new models have multiplicative creation, a cosmological scale factor $S(t) \propto t^m$, *and are spatially flat; a multiplicative steady state model also satisfies the hypotheses. How these models affect the temperature of the Earth and the cosmological deceleration parameter is important.*

GRAVITATIONAL and cosmological physics yields three parameters that characterise the macroscopic structure of the Universe—the Hubble constant H, the constant of gravity G, and the average matter density ρ. These parameters are measured in units of mass length and time, a unit independent measure is obtained by comparing them to microscopic parameters of the same dimensions. If m is the mass of an electron, $-e$ its charge, and c the velocity of light, such unit independent measures are

$$\frac{mc^3}{e^2H} \simeq 6\times10^{40}, \quad \frac{e^2}{Gm^2} \simeq 4\times10^{42}, \quad \frac{m^4c^6}{e^6\rho} \simeq 4\times10^{40} \qquad (1)$$

These ratios are pure numbers, characteristic of the Universe. They are exceedingly large and approximately equal (the equality could be improved by using other microscopic units).

There are two points of view on these coincidences. One is that physics contains arbitrary parameters. The Universe could be different—it just happens that in our world, these parameters have their observed values. One argument is[1,2] that for human life to evolve and ask why the Universe is as it is, these parameters must have values close to those observed; the Universe could be radically different but we would not be here. I feel these arguments are not convincing either at the technical or philosophical level. The second view is that these coincidences are due to some interconnection between microscopic and macroscopic physics. Eddington[3] sought to develop a theory of such a casual interconnection, Dirac's[4,5] approach is to acknowledge that although at present we do not understand this relationship, we can proceed by assuming that for all time

$$\frac{mc^3}{e^2H} \simeq \frac{e^2}{Gm^2} \simeq \frac{m^4c^6}{e^6\rho} \qquad (2)$$

and further, that any other large number of the order of 10^{40} is approximately equal to these parameters. Since the first parameter is essentially the age of the Universe in microscopic units all these parameters vary in time but remain equal to each other. This is the large number hypothesis.

Cosmological models and the large number hypothesis

The application of this hypothesis to cosmology restricts the class of possible world models described in atomic units by the Robertson–Walker metric

$$ds^2 = dt^2 - \frac{S^2(t)}{c^2}\left(\frac{dr^2}{1-kr^2/R_0^{\,2}} + r^2\,d\theta^2 + r^2\sin^2\theta\,d\varphi^2\right) \qquad (3)$$

where $S(t)$ is the scale factor, R_0 a constant length and

$k=0, +1$, or -1. This metric has at least two characteristic lengths, that are, in principal, empirically determinable (by using atomic clocks and sending light signals between three non colinear co-moving cosmological observers). They are the Hubble length L_H and the radius of curvature of the space t = constant L_S defined as

$$L_H = \frac{c}{H} = \frac{cS}{\dot{S}}\ ;\ L_S = \frac{R_0 S}{k},\ k \neq 0 \qquad (4)$$

Both these lengths are very large and vary as $S(t)$ varies. The large number hypothesis requires that they be proportional to each other, which requires

$$k \neq 0,\ S = S_0 t + S_1\ ;\quad k = 0,\ S(t) \propto t^m \text{ or } S(t) \propto \exp(t/t_0) \quad (5)$$

The first result is obvious, since if $k \neq 0$, $\dot{S}$ is constant. As the Universe is observed to be expanding, we can further impose $S_0 \neq 0$ and so S_1 can be absorbed into the zero of time measurement. There are then only two such models, the Milne model[4] $k = -1$, $S(t) \propto t$, and the recent Dirac[5] model $k = +1$, $S(t) \propto t$. If $k = 0$, L_S is not a measurable parameter, however, $S(t)$ is not an arbitrary function of t; to see this we invoke Milne's dimensional argument[6]. Another measurable parameter is the deceleration parameter

$$q = -\frac{S\ddot{S}}{\dot{S}^2} = q(t) \qquad (6)$$

This is a pure number. If q varies in time, there must exist a constant t_0 of dimension's time such that $q = q(t/t_0)$ The theory now contains a constant t_0 and a variable $S/\dot{S}$, but the large number hypothesis requires them to be proportional to each other, so either $S/\dot{S} \alpha\ t_0$, $S \propto \exp(t/t_0)$ or $q = S\ddot{S}/\dot{S}^2$ = constant. The second alternative gives the first solution if $q = -1$, otherwise $S(t) \propto t^m$ where $q = (1-m)/m$.

Turning now to equation (2) the first and second terms give $G \propto H$ so that in general G varies in time as measured in atomic units. The first and third conditions give $\rho \propto H$, but as the Universe expands, the number of particles in a co-moving volume $N_0 \propto \rho S^3$, hence $N_0 \propto HS^3$ which is general varies with time. Particles must, therefore, be created or annihilated, the exception being the original Dirac model $S(t) \propto t^{\frac{1}{3}}$. In Table 1 we list the Robertson–Walker models satisfying the large number hypothesis.

Table 1 Cosmological models satisfying the large number hypothesis*

Model	k	$S(t)$	H	G	N_0
Milne	-1	t	$1/t$	$1/t$	t^2
Dirac	$+1$	t	$1/t$	$1/t$	t^2
Steady State	0	$\exp(t/t_0)$	$1/t_0$	const	$\exp(3t/t_0)$
Power Law	0	t^m	m/t	$1/t$	t^{3m-1}
Original Dirac	0	$t^{\frac{1}{3}}$	$1/3t$	$1/t$	const

*The three models $S(t) = 1$, $k = 0, +1, -1$, are ruled out by the condition $H \neq 0$.

Field equations in Einstein units

To advance any further, it is necessary to impose some additional constraints on the theory. First, where is the matter created? In the standard steady state theory[7,8], the newly created matter is supposed to be created *uniformly* throughout space and time. Dirac has recently proposed that creation is multiplicative[5]—that is, new matter is created in proportion to existing matter; we shall accept this hypothesis. The empirical success of general relativity further led Dirac to hypothesise that this theory must remain valid for macroscopic physics, due allowance being made for the creation of matter, and was led to deduce the new model described above, $S(t) \propto t$, $N_0 \propto t^2$, we shall also retain this hypothesis; however, it hardly restricts the possible cosmological solutions, only the Milne model does not satisfy this constraint.

Since general relativity is to describe macroscopic gravitational physics, we work in Einstein units in which the macroscopic mass mN_0, the constant of gravity G, and the velocity of light c are constant. All we are doing here is to define as our unit of mass as (say) the mass of the sun, our unit of time is defined by a gravitational clock (say) the orbital period of the Earth, and the unit of length is defined from the unit of time and a defined constant velocity of light. In this set of macroscopic units, Einstein's equations

$$R_{ij} - \frac{1}{2} g_{ij} R + \Lambda g_{ij} = \frac{8\pi G}{c^2} T_{ij} \qquad (7)$$

are valid. However, since matter is being created, the number of elementary particles in the sun varies in time, so, too, do the mass m and charge e in these gravitational units, subject to the condition that mN_0 is constant.

If τ and ρ are time and distance in Einstein units, then if the Robertson-Walker metric

$$ds_E^2 = d\tau^2 - \frac{S^2(\tau)}{c^2}\left(\frac{d\rho^2}{1-k\rho^2/R_0^2} + \rho^2 d\theta^2 + \rho^2 \sin^2\theta d\varphi^2\right) \qquad (8)$$

is introduced into the field equation (7), we obtain the usual family of cosmological models. However, most of these are incompatible with the large number hypothesis, introducing two or more cosmological lengths that are not proportional to each other. The only admissible solutions are those that satisfy equation (5) of which there are just two.

Einstein models:

$$S = 1,\ k = +1,\ \Lambda = \frac{1}{R_0^2} = \frac{4\pi G\rho}{c^2},\ \rho\text{, constant} \qquad (9)$$

Einstein–de Sitter model:

$$S \propto \tau^{2/3},\ k = 0,\ \Lambda = 0,\ \rho S^3 = \rho_0\ ,\ \text{a constant} \qquad (10)$$

Large number hypothesis in Einstein units

The large number hypothesis shown by equation (2) is, of course, independent of any system of units. In Einstein units with G, c and ρ_0 constant this requires

$$H \propto \frac{m^3}{e^4}\ ,\quad \frac{e^8}{m^6} \propto S^3,\ \text{hence } H \propto \frac{1}{S^{3/2}} \qquad (11)$$

The Hubble constant H is not S'/S (the dash denotes differentiation w.r.t. τ). It is defined, and measured, as the constant of proportionality in the red shift luminosity distance relation. Besides the usual contribution due to expansion in τ time, there is a further contribution due to the change in frequency of a particular atomic transition as e and m vary in τ time, this frequency

$$\nu \propto \frac{m}{e^2} \propto \left(\frac{1}{m^2(\tau)S^3(\tau)}\right)^{1/4} \qquad (12)$$

The ratio of the frequency of radiation from a given transition in a distant source at time τ_1, to the frequency of radiation from the same transition as an observer is, therefore

$$\frac{\mu_1}{\mu_0} = \frac{S(\tau_0)}{S(\tau_1)}\left(\frac{m^2(\tau_1)\,S^3(\tau_1)}{m^2(\tau_0)\,S^3(\tau_0)}\right)^{1/4} \tag{13}$$

The source is at co-moving Einstein coordinate $(\rho_1\tau_1)$, the receiver at $(0, \tau_0)$, since the signal propogates along null geodesics we have

$$\int_0^{\rho^1} \frac{d\rho}{1-k\rho^2/R_0^2} = \int \frac{c\,d\tau}{S(\tau)}, \quad \tau_1 = \tau_0 - \rho\,\frac{S(\tau_0)}{c} + \ldots \tag{14}$$

and hence equation (13) becomes

$$\frac{\nu_1}{\nu_0} = 1 - \left(\frac{1}{4}\frac{S'}{S} - \frac{1}{2}\frac{m'}{m}\right)\rho_1\frac{S(\tau_0)}{c} + \ldots \tag{15}$$

Now ρ_1 is the coordinate distance, not the luminosity distance l_1, to leading order, however $l_1 = \rho_1 S(\tau_0)c$; to second order this relation is not valid due to the change in luminosity of the source in τ time, the change of $S(\tau)$, the curvature of spaces $\tau = \text{constant}$ and the creation of photons in the beam of radiation as it travels from the distant source to the receiver. These effects will be considered below when estimating the deceleration parameter for these models. To leading order the red shift luminosity distance relation is

$$cz = Hl, \; H = \left(\frac{1}{4}\frac{S'}{S} - \frac{1}{2}\frac{m'}{m}\right) \tag{16}$$

We can now combine this result for the Hubble constant in Einstein units with the result (11) $H \propto S^{-3/2}$ to obtain the two solutions that satisfy the large number hypothesis and Einstein's equation in Einstein units
Einstein Universe:

$$S = \text{constant},\; H = \text{constant},\; m \propto \exp(-\tau/\tau_0)$$
$$N_0 \propto \exp(\tau/\tau_0),\; e \propto \exp(3\tau/4\tau_0) \tag{17}$$

Einstein–de Sitter Universe:

$$S \propto \tau^{2/3},\; H \propto \tau^{-1},\; m \propto \tau^{-n},\; N_0 \propto \tau^{n},\; e \propto \tau^{(1-3n)/4} \tag{18}$$

where $n \neq -1/3$ but is otherwise arbitrary ($n = 1/3$ gives $H = 0$).

The cosmological models in atomic units

Having obtained the equations (17) and (18) in Einstein units we can transform them back to the more familiar atomic units (AMU) in which e, m, c are constant but G and ρ_0 are not. (We could have scaled Einstein's equations in Einstein units to obtain their equivalent form in atomic units by the conformal transformation $g_{ij} \rightarrow \beta g_{ij}{}^*$, and worked throughout in AMU: the results would, of course, be the same. However, we prefer to use Einstein as this emphasises the assumptions, and simplifies the analysis.) The AMU of length and time

$$l_A \propto \frac{e^2}{m} \propto (m^2 S^3(\tau))^{1/4} \tag{19}$$

varies in Einstein units but is by definition constant in AMU. All lengths and times in Einstein units must, therefore, be scaled by this factor to obtain their values in AMU, so that if t is atomic time
Einstein model:

$$dt \propto (m^2S^3)^{-1/4}d\tau \propto \exp(\tau/\tau_0)\,d\tau \tag{20}$$

Einstein–de Sitter model:

$$dt \propto (m^2S^3)^{-1/4}d\tau \propto \tau^{(n-1)/2}d\tau \tag{21}$$

These integrate to give
Einstein model:

$$t \propto \exp(\tau/\tau_0) \tag{22}$$

Einstein–de Sitter model:

$$t \propto \tau^{(n+1)/2} \; n \neq -1 \tag{23}$$

$$t \propto \ln\tau/\tau_0 \; n = -1 \tag{24}$$

Similarly, the metric in AMU is obtained by scaling the metric in Einstein units

$$ds_A{}^2 = \frac{ds_E{}^2}{(m^2S^3)^{1/2}}$$

yielding
Einstein model:

$$ds_A^2 = \exp(\tau/\tau_0)\left(d\tau^2 - \frac{1}{c^2}\left(\frac{d\rho^2}{1-\rho^2/R_0{}^2}\right) + \right.$$
$$\left. + \; (\rho^2 d\theta^2 + \rho^2 \sin^2\theta\, d\varphi^2)\right) \tag{25}$$

Einstein–de Sitter model:

$$ds_A^2 = \tau^{n-1}\left(d\tau^2 - \frac{1}{c^2}\left(\frac{\tau}{\tau_0}\right)^{4/3}(d\rho^2 + \rho^2 d\theta^2 + \rho^2 \sin^2\theta\, d\varphi^2)\right) \tag{26}$$

which gives the three solutions: the Dirac Creation Model (DC), the power law models (PL) and the Steady State theory with multiplicative creation (MSS)

$$\text{DC: } ds_A^2 = dt^2 - \frac{1}{c^2}\left(\frac{t}{t_0}\right)^2\left(\frac{dr^2}{1-r^2/R_0{}^2} + r^2 d\theta^2 + r^2 \sin^2\theta\, d\varphi^2\right),$$
$$N_0 \propto t^2,\; G \propto 1/t \tag{27}$$

$$\text{PL: } ds_A^2 = dt^2 - \frac{1}{c^2}\left(\frac{t}{t_0}\right)^{2m}(dr^2 + r^2\theta^2 + r^2 \sin^2\theta\, d\varphi^2),$$
$$N_0 \propto t^{3m-1},\; G \propto 1/t \tag{28}$$

$$\text{MSS: } ds_A^2 = dt^2 - \frac{1}{c^2}\exp(2t/t_0)\,(dr^2 + r^2 d\theta^2 + r^2 \sin^2\theta\, d\varphi^2),$$
$$N_0 \propto \exp(3t/t_0),\; G = \text{const} \tag{29}$$

Of the possible solutions listed in Table 1, only the Milne model $S \propto t$, $k = -1$ is excluded. The condition that the large number hypothesis be satisfied and that Einstein's equations be satisfied in Einstein units (G c, ρ_0 constant) does not lead to a unique cosmological model, but to two special cases, the Dirac creation cosmology and the steady state cosmology with multiplicative creation, and to a family of power law models $S(t) \propto t^m$. Indeed, even the Dirac creation cosmology is not unique since R_0 in the equation (27) is arbitrary. Only by introducing a theory of the creation process can we expect to narrow down the range of possible models, for example, if there has been no creation or annihilation of matter since the 'origin' of the Universe, the only viable model is the original Dirac model without creation $S(t) \propto t^{1/3}$. However, I see no metaphysical attraction in such a hypothesis, and in the absence of any empirical evidence, there is no way to differentiate between the models.

The black body temperature of the Earth

For all the models derived here, we can calculate the variation of the thermal equilibrium temperature of the Earth during its lifetime. This is not, however, necessarily the actual thermal history of the Earth since many factors, such as atmospheric composition, and albedo need to be considered, but it should give some indication of the consequences of these models for the terrestrial environment. The flux of radiation falling on the Earth varies for several reasons, (1) the Sun's luminosity is sensitively dependent on the value of G, and the mass of the Sun, (2) the Earth's orbit spirals outwards (or inwards) as the mass of the Sun and Earth and G vary, (3) the Sun evolves chemically. We shall neglect (3), at constant mass and G this corresponds to an increase in solar luminosity of about 35%.

The luminosity of a star (L) of about solar mass depends on its mass M and the constant of gravity G approximately as $L \propto G^7M^5$. Working in AMU we find that the equilibrium temperature

$$T_e \propto \left(\frac{L}{r_A^2}\right)^{1/4} \propto \left(\frac{G^7N_0^5}{r_A^2}\right)^{1/4} \qquad (30)$$

where r_A is the radius of the Earth's orbit in AMU. Provided the newly created matter is created with the same velocity as its surroundings, thereby not exerting a drag on the Earth's orbit[9], the radius of that orbit is constant in Einstein units. Its value in atomic units is simply obtained by scaling by the factor $(m^2S^3)^{1/4}$ of equation (11); using the results in equations (27) to (29) gives

$$\text{DC: } T_e \propto t^{1/4},\ \text{PL: } T_e \propto t^{(9m-8)/4},\ \text{MSS: } T_e \propto \exp\left(\frac{9}{4}Ht\right) \qquad (31)$$

The estimated value of the Hubble constant is about 5×10^{-11} yr^{-1}, and the age of the Earth is about 5×10^9 yr, hence the ratio of equilibrium temperature today to when the Earth was formed is

$$\text{DC: } \frac{T_e}{T_0} \propto \left(\frac{4}{3}\right)^{1/4},\ \text{PL: } \frac{T_e}{T_0} \propto \left(\frac{4m}{4m-1}\right)^{(9m-8)/4},$$
$$\text{MSS: } \frac{T_e}{T_0} = \exp\left(\frac{9}{16}\right) \qquad (32)$$

Inasmuch as any conclusion can be drawn from climate studies, the flux of radiation falling on the Earth has increased. Indeed, if it was ever less than 90% of its present value, the Earth would now probably be completely ice covered[10]. This is a problem for standard theory which predicts a solar constant some 70% or so of the present value during the early history of the Earth[11]. If $m < 8/9$ the power law models yield a decreasing solar flux. (These models would not, however, explain the low neutrino flux since the evolutionary lifetime of a star $\propto L/M \propto t^{12m-11}$ so that such models would be more evolved than the standard model giving an increased solar neutrino flux.

The cosmological deceleration parameter

As the intrinsic luminosity of a star varies as the Universe evolves, so too will the intrinsic luminosity of a galaxy. This 'evolutionary effect' will manifest itself in the observed departures from the Hubble relation, through the deceleration parameter. While a detailed analysis requires a study of stellar and galactic evolution in these cosmological models, some idea of the observational consequences is obtained by assuming $L_{\text{galaxy}} \propto L_{\text{star}} \propto G^7M^5$.

Consider a galaxy at coordinate distance r_1, the energy per unit area received at the origin of coordinates at time t_0 (measured in atomic units) is[12]

$$P = \left(\frac{L(t_0)}{4\pi S^2(t_0)r_1^2}\ \frac{S^2(t_1)}{S^2(t_0)}\right)\left(\frac{N_0}{N_1}\right) \qquad (33)$$

where $L(t_1)$ is the luminosity of the source at the time of emission t_1, and the extra factor N_oN_1 is due to the multiplicative creation of photons in the beam on its journey from source to receiver. The coordinate distance r_1 satisfies

$$\int^{r_1} \frac{\mathrm{d}r}{1-kr^2/R_0^2} = \int_{t_1}^{t_0} \frac{c\,\mathrm{d}t}{S(t)},\ r_1 = \frac{zc}{S(t_0)}\left(1-\frac{1}{2}(q_0+1)z+\ldots\right. \qquad (34)$$

where z is the red shift of the source $(1+z)=S(t_0)/S(t_1)$, and $q_0=-S\ddot{S}/\dot{S}^2$ is the deceleration parameter at $t=t_0$. Equations (33) and (34) yield the magnitude redshift relation

$$m_s = -2.5\log\left(\frac{L(t_1)}{L(t_0)}\right) + 5\log z + 2.5\log(1-z)$$
$$-5\log H + \text{const} \qquad (35)$$

This relation is valid for all the models considered here, the value of m does not appear explicitly as the term

$$\frac{N_0}{N_1} = \left(\frac{S(t_0)}{S(t_1)}\right)^{(3m-1)/m} \simeq \left(1+\frac{3m-1}{m}z\ldots\right)$$
$$= (1+(2-q_0)z+\ldots \qquad (36)$$

and the terms involving q_0 exactly compensate. The same is true for the MSS model. Neglecting galactic evolution, all these models have an effective deceleration parameter $q_e = +2$, the particular characteristics of the model only enter through the evolution of the galaxy. If we assume that $L_{\text{galaxy}} \propto L_{\text{star}}$, then for the power law models

$$\frac{L(t_1)}{L(t_0)} = \left(\frac{t_1}{t_0}\right)^{(15m-12)} = \left(\frac{S(t_1)}{S(t_0)}\right)^{(15m-12/m)}\ 1+\frac{15m-12}{m}z+\ldots \qquad (37)$$

and again this result holds for the MSS model with $m\to\infty$. Including this estimate of the evolutionary effect, we find an effective deceleration parameter

$$q_e = 2-\left(\frac{15m-12}{m}\right) = \frac{12-13m}{m} \qquad (38)$$

For the DC model $q_e=-1$, for the original Dirac model without creation $m=1/3$, $q_e=23$, for the MSS model $q_e=-13$, for the constant Earth temperature model $m=8/9$, $q_e=0.5$. It would appear that there are models whose predictions are not incompatible with observation.

Conclusions

Assuming the validity of the large number hypothesis, multiplicative creation, and that general relativity is satisfied in Einstein units, we find a family of possible cosmological models. Two of these are the original Dirac model without creation and the new Dirac model with creation, but other solutions exist with $S(t) \propto t^m$, m arbitrary, and a multiplicative steady state theory. Further restrictions have to be imposed on the theory before this class of solutions can be narrowed down to one model.

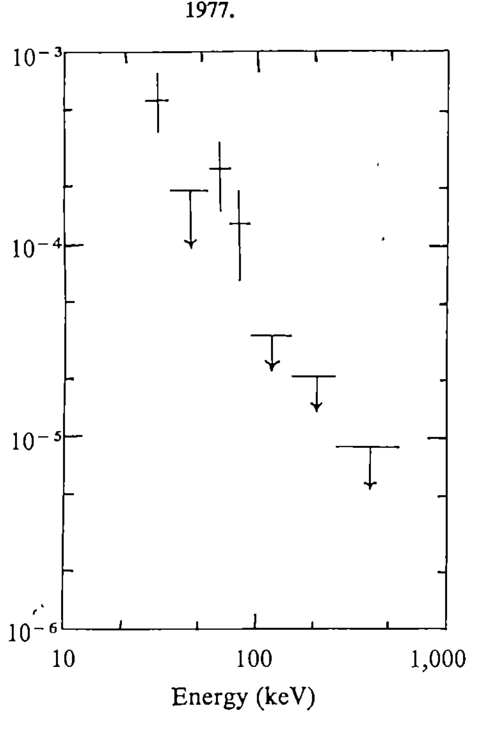
A line feature at 64 keV in the X-ray spectrum of Her X-1

TRUMPER and his colleagues[1] have reported observations which give evidence of a hard X-ray line feature in the spectrum of the pulsed flux of Her X-1. They suggest that this is cyclotron radiation from the poles of a neutron star. We discuss here some similar measurements made by the Imperial College Scintillation Telescope (ST) on Ariel 5 during a visit to the Hercules region, scheduled many months in advance of the observation. The binary system Her X-1 is known to emit X rays for at least 10 d in its 35-d cycle and our measurements were made during the ON period 3–13 February 1977.

The ST covers the energy range 26 keV to 1.2 MeV and consists of a CsI(Na), actively collimated detector crystal of 8 cm^2, offset from the satellite spin axis by 3°. Further details of the instrument and our observational technique can be found elsewhere[2]. We observed Her X-1 with the ST instrument in spectral mode for 2 d on the rising side of the light curve and 4 d on the falling side. This data has a time resolution of 8 min and thus we can only discuss the time averaged spectrum. Data from both epochs have been summed to obtain the best statistics and the resulting pulse height spectrum is shown in Fig. 1. All upper limits are 2 standard deviations (s.d.). It is clear from Fig. 1 that there is a significant flux excess in the 56–94 keV band.

To deconvolute this data from the detector response, a three-component spectrum was used consisting of a thermal bremsstrahlung component of $kT \sim 4$ keV, a line component at a variable energy, and a hard, power-law tail consistent with our upper limits. This gives the most conservative estimate for the significance of the line feature in the data. The relative intensities of the three components were varied, folded through a detector interaction matrix (as explained in ref. 2) and compared with the pulse height spectrum until a best fit was achieved. The fit was constrained to lie immediately below all the 2 s.d. upper limits. This spectrum was then used to deconvolute our data points and the result is shown in Fig. 2. Again all upper limits are 2 s.d. We believe that any spectrum consistent with the points shown in Fig. 2 would produce the pulse height spectrum observed. The fitted spectrum of Boldt *et al.*[3] from rocket flight data has also been shown in Fig. 2. Their absolute flux has been reduced by a factor of two to fit with our point at 30 keV. This fitting has no effect on the intensity of the line at 64 keV due to the steep nature of this part of the spectrum.

Fig. 1 The pulse height spectrum (converted to an energy scale) obtained from Her X-1 with the hard X-ray detector on Ariel 5 by combining data from the periods 4–6 and 9–13 February 1977.



Assuming the spectral feature evident in Fig. 2 is the result of a narrow line, we can set limits to its position by considering the detailed spectral response of our channels. This yields an energy of 64±6 keV at 1 s.d. Alternatively, by assuming a broader line centred near the mid-point of our channel, we can find an upper limit for its FWHM. This gives 16 keV at 1 s.d. Our estimate for the line intensity is 0.017 ± 0.007 photons cm^{-2} s^{-1} and this value is relatively insensitive to variations in the assumed underlying spectrum used for unfolding the results. The error is calculated for counting statistics only. Separate analysis of data from the rising and falling side of the X-ray light curve both yield evidence for the line feature.

The observations of February 1977 can be compared with a previous shorter observation[4] made by the same instrument in March 1975 during the early part of the ON phase. Identical analysis of these earlier data reveal a flux in the 26–34 keV band which is three times higher than the new flux. But no spectral feature is apparent at 64 keV and there is only a 2% probability that the line feature was also three times brighter than the new intensity. A line of intensity equal to the one reported here would not have been detectable due to the shorter observation time.

To explain the line, consider the usual model for X-ray emission from Her X-1 as being due to the infall of material near the surface of a neutron star after pushing its way down the polar funnels of the intense magnetic field. Correcting the line energy for gravitational red-shift (taking the origin of emission as 1.2×10^6 cm for a $1 M_\odot$ object) yields 73.1 keV as the initial energy. Classical cyclotron emission theory gives $h\nu_0 = (eHh/2\pi m_0 c) \times \sqrt{}(1-\beta^2)$ for the energy of first harmonic emission in a field H where β is the electron velocity expressed as a fraction of c and m_0 is its rest mass. This leads to a field strength estimate of $H = 7.3 \times 10^{12}$ G. At this field strength, however, the De Broglie wavelength of a 73 keV electron is four times its cyclotron radius and a relativistic, quantum mechanical treatment would seem more appropriate. Johnson and Lippmann[5] find total energy eigenvalue solution to Dirac's equation given by $E = \pm[c^2 p_{\parallel}{}^2 + m_0{}^2 c^4 + e\hbar cH (2n+s+1)]^{\frac{1}{2}}$, where $s = \pm 1$, the electron spin state, n is the principal quantum number and $p_{\parallel}$ is momentum parallel to **H**. Supposing that both parallel and anti parallel spin states arise while the material is falling into the polar funnels, $s = +1 \rightarrow s = -1$ transitions may be expected to occur, leading to energy release ΔE where $E_{\mathrm{i}}{}^2 - (E_{\mathrm{i}} - \Delta E)^2 = 2e\hbar cH$. E_{i}, the initial energy, is estimated as the sum of rest mass energy plus energy in the spin-field interaction plus thermal energy and we take the last of these contributions as 13 keV, based on a previous data fit of Carpenter *et al.*[4]. A value $H = 6.9 \times 10^{12}$ G results. Lodenquai *et al.*[6] find various allowed angular momentum states in a more complete, but non-relativistic treatment. Use of their work and the assumption of angular momentum transitions would lead to a field value roughly comparable with

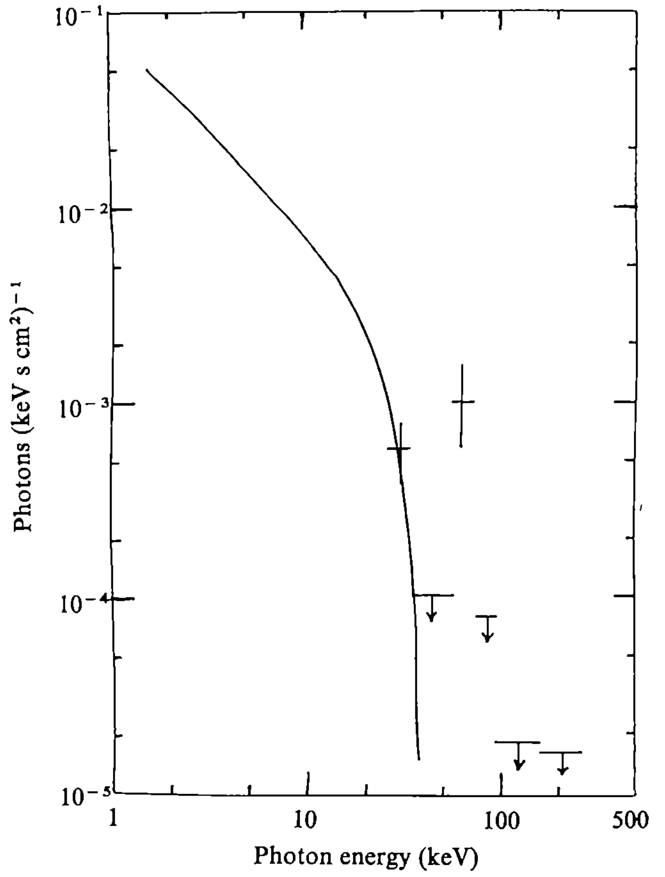


Fig. 2 The spectrum of Fig. 1 unfolded as described in the text. Also shown, as a continuous line, is the best fit spectrum from the proportional counter data of Boldt *et al.*[3] reduced in absolute intensity by a factor of two.

the above estimates. Note that a line arises naturally in the quantum mechanical treatment, rather than the wide spread implied by the $\sqrt{(1-\beta^2)}$ factor in the classical treatment. In fact, putting $\Delta E \propto \Delta H$ and assuming a dipole field implies an emitting region depth 8% of a neutron star radius in size if we take our observations of the line width. Also note that high electron kinetic energies and, by implication, X-ray continuum radiation at appreciable levels around 100 keV are not necessary. A classical treatment of the cyclotron self-absorption effect suggests that for the observed flux values, escape of the X rays considered is not a problem.

An alternative explanation in terms of radioactive decay of nuclides produced by explosive nucleosynthesis during neutron star formation more than 10^4 years ago is less promising. We use Clayton's[7] estimates of supernovae yields required to give the ^{60}Ni Solar System abundance, with 50% produced via the ^{60}Fe progenitor, which decays with a 3×10^5-yr half life. The ^{60m}Co decay to ground state within this chain is via a 58.6-keV ($\sim$ 50 keV after redshift) line, provided the internal conversion branch in atomic Co is inhibited by the degenerate gas conditions at the neutron star surface. A low Her X-1 distance estimate of 600 pc is then required to get $\sim 4\times10^{-5}$ cm^{-2} s^{-1} photons at the Earth, well short of the observed flux. Furthermore, a magnetospheric controlled screening process would need to be invoked to explain the occurrence of the line in the pulsed component and this would further decrease the predicted flux. No other process seems as likely as the one discussed. But a lack of temporal variation in the line flux would perhaps favour an explanation in terms of radioactivity, in which case the estimates for nuclide production from supernovae must be considerably revised.

A search for the equivalent proton cyclotron transition at 274 Å (after redshift) would be interesting. Radiation from such a line is likely to be highly perturbed by the surrounding plasma, however. If our explanation of the observations is correct, a new way of exploring pulsar magnetic fields is opened up.

We thank A. R. Edmonds and H. Elliot for stimulating discussions, the Appleton Laboratory for satellite operations and the SRC for funding the project.

Relation between metallicity and multiplicity for solar type stars

It has been suggested that the ratio of heavy elements to hydrogen (metallicity) in a contracting interstellar cloud might affect the process of star formation. There is now statistical evidence for solar type stars that the metallicity of a forming stellar system is correlated with the multiplicity of the resultant system and may actually determine whether the system will be multiple or single.

The most direct and complete data on the multiplicity of solar type stars are given by Abt and Levy[1]. The δm_1 index[2,3] is thought to provide rather precise determinations of the relative metallicities of late F dwarfs and subgiants. Lindemann and Hauck[4] give photometric data sufficient to calculate δm_1 (β) for 87 of Abt and Levy's 135 stars, and $\delta m_1(b-y)$ for 27 more. Two of the stars must be omitted because they are too cool for β or $b-y$ to be reliable. Of the 112 remaining stars with available δm_1, Abt and Levy (their Table 2) describe 15 as having a 'probable' or 'possible' constant or variable velocity. Omitting these slightly uncertain cases from consideration, there are 97 stars with reliable values of δm_1 and definite statements whether their radial velocities are constant or not. The latter are interpreted as multiple systems while the former may be single stars, stars with low mass secondaries and/or extremely long periods, or close binaries viewed pole on.

The 97 stars divide into three categories of metallicity: (1) $\delta m_1 \leqslant 0.000$, the mean metallicity of the Hyades cluster stars or higher; (2) $0.000 < \delta m_1 \leqslant 0.030$, metallicities ranging from half that of the Hyades stars up to that of the Hyades stars; (3) $\delta m_1 > 0.030$, metallicities less than half that of the Hyades stars.

There are seven stars in the metal-rich group (1): six have a variable velocity (interpreted as multiple); one has a constant velocity and a companion with a common proper motion (CPM) and is interpreted here as a multiple system. None has a constant velocity and no known or suspected companion (interpreted as 'single?').

There are 74 stars in group (2): 35 have a variable velocity (multiple); nine have a constant velocity and a CPM companion or are known members of a visual binary system (multiple); 30 have constant velocities and no known or suspected companions (single?).

There are 16 stars in the moderately low metallicity group (3): one has a variable radial velocity (multiple); two have constant velocities and either has a CPM companion or is a known member of a visual binary (multiple); 13 have constant velocities and no known or suspected companions (single?).

Table 1 Multiplicity for three categories of metallicity

	$\delta m_1 < 0.000$		$0.000 < \delta m_1 < 0.030$		$\delta m_1 > 0.030$	
	Multiple	Single	Multiple	Single	Multiple	Single
High velocity	0	0	3	3	0	5
Low velocity	7	0	41	27	3	8
Combined	7	0	44	30	3	13

Eleven of the 97 stars are intermediate (not extreme) 'high velocity' stars with space motions in excess of 63 km s^{-1}. It has long been known that high velocity stars tend to be single and also that they tend to have low metallicity. Table 1 emphasises that a metallicity–multiplicity correlation exists within both the high velocity and low velocity groups. In other words, it is a phenomenon of both population 1 and population 2 stars. (It is important to determine whether the unresolved combination of the colours of two members of a close binary will produce an artificially small δm_1 leading to a false interpretation that the pair is richer in heavy elements than they actually are. Calculations of various combinations of the observed colours of apparently single, constant velocity stars suggest that this is not the case.) We conclude that the chemical composition of the star forming cloud is closely related to the probability of forming a multiple system.

There is new evidence from spectral quantification[5] and from spectral classification[6] that the Sun has the same metallicity as the mean of the Hyades cluster stars. This result, acceptance of a metallicity–multiplicity correlation, and the awareness that the internal scatter in the δm_1 values is about 0.01 magnitudes, suggest that all solar type stars of $\delta m_1 \lesssim 0.020$ (which is about $\frac{2}{3}$ the solar metallicity or greater) are multiple systems with the observed constant velocity systems being either systems viewed pole on or systems with low mass secondary stars or planets. This inference is consistent with Abt and Levy's conclusion that single stars are rare among low velocity stars.

The possibility also exists that all solar type systems of whatever metallicity form as multiples with the lower metallicity systems (including population 2) tending to have large mass ratios and being more likely to have planets as secondaries. Carried to the extreme, this speculation implies that the hypothetical population 2 planetary systems might have given rise to life more than 5,000 Myr before our Sun formed.

Cosmic rays and and ancient catastrophes

A NUMBER of suggestions have been made[1–3] that encounters of the solar system with extra-solar phenomena in earlier epochs led to climatic and biological catastrophes. Most recently Whitten *et al.*[4] and Clark *et al.*[5] have drawn attention to the role of nearby supernovae (within ≃ 10 pc) from which catastrophic effects are expected (primarily the depletion of the atmospheric ozone layer and consequent transmission of damaging solar ultraviolet.) Whitten *et al.* estimate the probability of an encounter within a period of 10^8 yr to be 1–5% and Clark *et al.* calculate 50% for the same quantity. In this letter, we argue that it is likely that rare and very big solar flares, and their attendant cosmic-ray fluxes, will give even more dramatic effects. This idea is not new, in that Reid *et al.*[6] have drawn attention to the effect of solar flares on the evolution of life, but here we endeavour to estimate the likely frequency of solar flares of sufficient strength to have significant effects. Furthermore, we draw attention to the 'explosion' at the galactic centre postulated by some[7] to have occurred about 10^7 yr ago; if this actually took place then its effect too would have been important and exceeded likely supernova phenomena.

In view of the fact that the Sun is the nearest active astronomical object, it is clearly necessary to examine its activity characteristics in detail before going further afield. There is a wealth of data on solar flares and, for the past 35 yr, cosmic rays from the Sun have been recorded, with an increasing degree of completeness. Measurements have been made of particles at ground level, at a variety of altitudes and, recently, outside the atmosphere with satellites. In each case, data have been collected at various geomagnetic latitudes. We have summarised the published data (most of it relevant to high galactic latitudes where the geomagnetic cut off is small) in Fig. 1. The energy density received at the top of the atmosphere is taken as the relevant parameter (defined as integrated energy in the flare for particles above a threshold energy per unit area: erg cm^{-2}) and its frequency distribution is taken for two periods (1956–1960)[8] and (1961–1972)[9]. The fluxes for 1956–1960 refer to a threshold of 100 MeV and the corresponding fluxes for protons above 20 MeV will be higher by a factor of the order of 5. A comment is necessary about the magnitude of the threshold energy relevant to the present analysis. A prominent effect is the destruction of the ozone

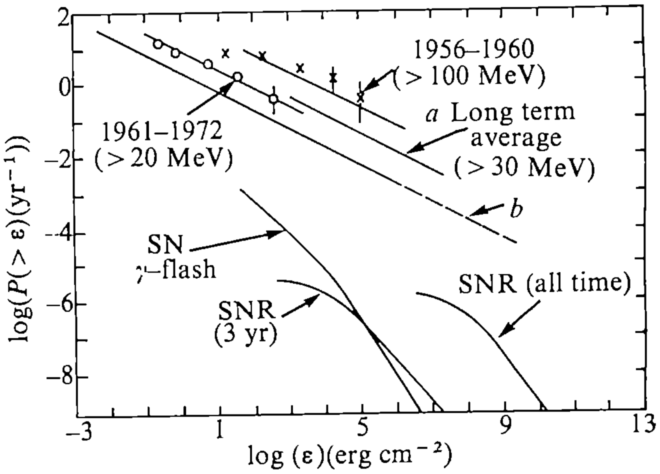

Fig. 1 Integral frequencies of solar cosmic-ray bursts at the Earth. The abscissa is the energy density in the burst and relates to the top of the atmosphere. Line *a* is a rough estimate of the long period average burst frequency (for energies above ~ 30 MeV) and is derived from measurements made on protons during the very active period 1956–1960 and during the most recent solar cycle 1961–1972 (the latter being of apparently rather average solar activity as judged by the mean sunspot numbers). Most of the particles under consideration normally arrive in the polar regions. Line *b* represents the frequency distribution when the burst energy density is averaged over the Earth's surface. SN γ-flash denotes the frequency distribution of energy deposition from the γ-ray flash from supernovae (using the result of Clark *et al.* 1977, for a supernova at 10 pc). SNR (3 yr) and SNR (all time) represent energy deposition over a 3-yr period, and integrated over the whole time, respectively, from protons when the Earth is immersed in a supernova remnant. *P* is probability and ε the energy density.

layer by NO produced after ionisation of the stratosphere[10] and the incident proton energy necessary to reach the appropriate levels in the stratosphere is $\simeq$ 30 MeV. Thus, an energy threshold of 20 MeV is only a little low for the necessary limit.

Two features are apparent in Fig. 1: there is a large difference in the absolute frequencies and the slopes of the variations are very similar in the two cases. The disparity in absolute frequencies relates to the difference in general solar activity in the two periods. The interval 1961–1972 covers the most recent solar maximum period together with the previous solar minimum and 1956–1960 comprises the corresponding previous solar maximum. The mean sunspot numbers are relevant; Allen[11] quotes $R_m = 110.6$ for the solar maximum in 1968.9 and $R_m = 201.3$ for 1957.9 to be compared with an overall average $R_m \simeq 112$ for the last 270 yr, the period over which reliable measurements have been made. There is, thus, some evidence for the frequency of bursts of solar cosmic-ray particles arriving at earth being strongly dependent on mean sunspot number. It is interesting that an analysis by Schove[12] suggests that only two periods, centred on 1372 and 1558 had similarly high sunspot numbers to 1956–1960. Thus, activity on the scale of 1956–1960, although rare is almost certainly not unique.

Remembering that the 1956–1960 data refer to energies above 100 MeV and that the contributions to $P(>\varepsilon)$, probability (> energy density), from the different cosmic ray flare magnitude ranges are additive we estimate that the very long term average for $P(>\varepsilon)$ and proton energies above 30 MeV is at least as high as line *a* in Fig. 1. There seems to be evidence for an emprical power law for $P > \varepsilon$ over seven orders of magnitude and we feel that this can probably be extended by at least several magnitudes more.

The region of interest with respect to supernovae is indicated in Fig. 1 by the line 'SN—γ flash'. The energy density of 10^6 erg cm^{-2}, corresponding to one event in 10^8 yr, is the value adopted by Clark *et al.* for γ rays from a supernova explosion at a distance of 10 pc and we have calculated the values for various distances to give the line. The interesting energy region considered by Clark *et al.* (10^8 erg cm^{-2}) is only a little way beyond the highest detected flare energy and extrapolation over this small energy range can surely be made. The extrapolation of line *a* itself is not immediately relevant, however, because the effective area over which the indicated energy density acts is not the full area of the earth, the reason being the shielding introduced by the Earth's magnetic field. As a very conservative figure we assume that the low energy particles in question arrive only at geomagnetic latitudes above 70°, where the average geomagnetic cut-off rigidity is only ~ 0.15 GV (it is permissible to use this value for a proton energy threshold of 20–100 MeV because the large cosmic-ray flares have rather flat energy spectra at energies below 200 MeV, or so). The operative area is ≈3% of the total. Using this factor the effective density averaged over the whole Earth is as shown in line *b*.

Another phenomenon is also relevant: the reversing, during past epochs, of the Earth's magnetic field[6]. During the period when the field is small, and the cutoff rigidity likewise, the flare particles will blanket the Earth completely. A very approximate analysis gives an effective average again not far from line *b* (we are indebted to C. J. Hatton and R. W. Girdler for discussions on these points).

Figure 1 also indicates that significant solar flare effects (similar to SN at 10 pc) will be expected about every 10^3 yr—much more frequently than expected for close supernovae—and, indeed, considerably stronger effects are likely on a time scale of 10^5 yr.

An important question is whether there is supporting evidence from other stars for the emission of energetic flares (and cosmic rays from them). Although in many solar flares the particle energy is only ≈1% of the total flare energy, in the largest cosmic ray flares, the particle energy seems to approximate to the optical energy[13] (≈ 10^{32} erg). Thus, the extrapolation is only to some 10^{34} erg or so in total energy in order to be well inside the SN region. There is little doubt that stellar flares do give cosmic-ray energies in this region. Lovell[14] has summarised the evidence for cosmic rays from M- and K-stars and shown that their flare energies are in the range 10^{33}–10^{37} erg. These flare stars are, of course, in different parts of the evolutionary path from the sun but Lovell makes a strong case for the same flare mechanism being operative in M-, K- and main sequence stars.

It is possible, in principle, to set limits to the frequencies of large optical and cosmic-ray solar-type flares from other data: the cosmic-ray flux in ancient times inferred from analysis of lunar samples, deep-sea sediments, etc. and the frequency of magnitude changes (from the associated optical flares) in main sequence stars. The situation with ancient cosmic-ray fluxes seems to be that the average flux has remained constant within a factor of 2 over the past 10^9 yr and the flux over the past 400 yr is within 10% the same as that over the past 4.10^5 yr (ref. 15). Although the bursts only last for the order of days or hours their intensities would be so high (10^4 times 1 yr galactic flux at 3×10^9 erg cm^{-2} for the linear extrapolation in Fig. 1) that they would contribute to long period averages. It is likely, therefore, that line *b* could continue to about 10^9 erg cm^{-2} without producing conflict with the ancient cosmic-ray measurements but above that it seems necessary to have a somewhat more rapid fall off.

There is, however, one set of measurements which do not fit into this pattern. These are from the studies of ^{10}Be and ^{26}Al in sea sediments[16,17] which seem to show a 10-fold increase in cosmic-ray intensity for a period of $\sim 10^6$ yr some 2.5×10^6 yr ago. Such an increase could be due to a small number of large bursts spaced over the period and if true would correspond to an extrapolation of line *b* without reduction.

The situation with respect to magnitude changes of main sequence stars is not very clear. It has been pointed out that the biggest flares (in 1956–1960) seemed to have high conversion efficiencies to cosmic rays so that the optical flare energies were, like the cosmic-ray energies, ~ 10^{32} erg. Presumably, for larger flares similar high efficiencies would result, so that, in order to achieve effects similar to SN at 10 pc, very infrequent optical flare energies of 'only' 10^{33}–10^{34} erg would be required. Flaring to this extent would seem to produce negligible magnitude changes in a reasonable sample of nearby stars. Continuing to a flare energy of ~ 3.10^{38} erg, a factor of $\sim 10^5$ beyond the SN threshold, if the average large optical flare lasts ~ 1 d only, 10^5 stars (out of 1.5×10^{11} stars in the Galaxy) should change by ~ 1 mag for 1 d yr^{-1}. It seems likely that such a low frequecy of flaring of this magnitude would not have been seen. Thus, the extrapolation of line *b* is allowable from astronomical data.

At this stage, it is obvious that the frequency of SN-equivalent cosmic-ray bursts is very high; some five orders of magnitude greater than calculated for SN at 10 pc. Thus, the effects postulated for SN would seem to occur with a very high frequency ($\simeq$ every 1,000 yr). In fact, we feel that much bigger bursts are probably required in order to have a really large effect on the ozone layer in the upper atmosphere[6] and a frequency of ~ 1 per 10^5 yr would seem more appropriate. Although this corresponds to a large extrapolation of line *b* there is a further large factor in hand because large bursts seem to be repetitive within the time constant (a few yr) for atmospheric ozone.

Reverting to supernovae, there is also the effect mentioned by Clark *et al.* of the increased cosmic-ray flux encountered when the solar system is inside a supernova remnant. The variation of cosmic ray intensity with time is the subject of conjecture; here we follow Clark *et al.* and adopt an increase over the local galactic intensity by 10^2 for the stage when the SNR radius is 10 pc. Assuming that the SNR merges into the I.S.M. when the radius is ~ 50 pc, the energy density over a 3-yr period (the approximate relaxation time of the atmosphere for O_3 production) follows the variation marked SNR (3 yr).

Allowance has been made for the lower efficiency of a galactic cosmic ray-type spectrum (of γ-rays) for depositing energy in the region of the atmosphere populated by O_3 (a factor of $\sim$ 25 down in energy density).

Also indicated in Fig. 1 is the energy density integrated over the whole of the SNR (SNR *p* (all time)). This variation would be relevant to those biological processes involving gradual reduction in quality over many generations.

It is interesting to estimate the likely radiological dose rate at the Earth's surface from the big solar flares. The galactic flux generates ~ 30 mR yr^{-1} at ground level (corresponding to $\sim 10^{-2}$ erg cm^{-2} s^{-1} of incident energy. Line *b* extrapolated indicates that a dose of 10^{11} erg cm^{-2}, corresponding to 10^4 R, would occur $\sim$ every 10^5 yr. Allowing for the eventual undoubted fall-off in $P(>\varepsilon)$ below the extrapolated line such a dose (lethal even to very primitive forms of life) would probably still occur more often than once every 10^8 yr. Such large flux densities do not necessarily indicate flares larger by many orders of magnitude compared with those observed in 1959. More likely would be situations where flares just a few orders bigger occurred at a time when a favourable (?) magnetic field geometry focused a significant fraction of the ouput onto the Earth.

Finally, attention is directed to a quite different phenomenon: the possibility of extremely energetic bursts from the galactic centre. Briefly, there is the possibility that the 3 kpc 'ring' is due to a radially symmetric explosive event in the galactic nucleus. With the ejection of $\sim 2 \times 10^8 M_\odot$ the initial energy is at least 3×10^{58} erg (ref. 7). On this model, the explosion occurred 12–13 × 10^6 yr ago (or earlier if there is oscillation of the ring). If the explosion resulted from the collapse of a very massive object then γ-ray emission would be very likely and, according to Colgate[18], the fraction of energy in this form would be large. Extrapolating from the value for less massive objects we take $f \sim 10^{-3}$ giving $\simeq 10^{55}$ erg in γ-rays. If $\sim 10\%$ of galaxies were to give bursts of this type then γ-ray bursts would occur at about the observed frequency.

With the γ-flash from the galactic centre the energy density at the Earth is $\sim 10^9$ erg cm^{-2}, a value that again exceeds the flux from local supernovae.

In conclusion, in addition to close supernovae, solar flares and explosions at the galactic centre should be borne in mind when considering possible catastrophes experienced by the Earth in its history. A more detailed study of solar and stellar flare data and ancient records of solar activity would appear to be profitable.

We acknowledge with gratitude discussions with D. H. Clark, W. H. McCrea, K. O'Brien, J. L. Osborne and F. R. Stephenson. The referee is thanked for very helpful remarks and criticisms.

Tunguska's comet and non-thermal ^{14}C production in the atmosphere

THE dramatic explosion on 30 June 1908 over Tunguska, Siberia continues to generate a wealth of literature on the supposed mysterious nature of the phenomenon. Hughes[1] recently summarised the generally convincing case for the hypothesis, first put forward by Whipple[2] and Astapovich[3], that a comet collided with the Earth's atmosphere. Opposition to this theory and consequent support for less conventional hypotheses involving black holes[4], almost critical masses of extraterrestrial fissionable material[5], anti-matter bodies[6] and alien spacecraft[7] have been based substantially on the non-observance of the comet before impact, the explanation of height of the explosion above the Earth's surface, the composition of the glassy spherules found at Tunguska and finally, and of most importance, the apparent occurrence of nuclear phenomena in the explosion as indicated by the subsequent enhancement of radiocarbon in the atmosphere. In the following, we discuss the first and last of these points which are clearly the most important.

Ben-Menahem[8] re-analysed the old seismograms of the Tunguska event and deduced the parameters of the original explosion by comparing the old data with contemporary records of the seismic and acoustic effects of recent nuclear air explosions. He concluded that the main explosion had an energy of $(5 \pm 1) \times 10^{23}$ erg and occurred at a height of 8.5 km. The size of the incident body can be estimated by assuming that its original kinetic energy was entirely converted into explosive energy. Krinov[9] found the geocentric velocity to be between 28 and 50 km s^{-1}, Levin[10] gave a geocentric velocity of 47 km s^{-1}. This latter value gives the body a mass of 5 × 10 g. Assuming the body is a cometary nucleus, of density 1 14 g cm^{-3} (ref. 11) its equivalent diameter is found to be 40 m. The absolute visual magnitude, m_0 of a comet of mass M (its magnitude 1 AU from both the Sun and Earth) is given by[12]

$$\log_{10}(M \text{ in g}) \simeq 21 - 0.4\, m_0 \qquad (1)$$

so the Tunguska comet had $m_0 = +26$.

The apparent magnitude, m of the comet when it is a distance r AU from the Sun and Δ AU from the Earth is given by[12]

$$m = m_0 + 5 \log_{10} \Delta + 10.5 \log_{10} r \qquad (2)$$

The two equations given above are mean, rule of thumb relationships obtained by considering the observed parameters of a great many comets. Some comets are notorious for departing from expected behaviour but in the absence of any observations of the Tunguska comet we can only assume that it was one of the more well behaved members of its species and obeyed the equations given.

Table 1 Apparent magnitude, m and time to impact t of the comet as a function of its distance from the Earth

Δ(AU)	r(AU)	m	t(min)
0 002	1.0	12 4	104
0 001	1 0	10 9	51
0.0005	1 0	9 4	24
0.0002	1.0	7 4	8
0.0001	1 0	5.9	3

Values of m for certain specific values of Δ are given in Table 1. Also given in Table 1 is the time t taken by the comet to travel, at 47 km s^{-1}, from a point Δ AU away from the Earth to the Earth's surface At the turn of the century comets were usually discovered at magnitudes around +11. The Tunguska comet is only brighter than this value for about 1 h before it impacts with the Earth, ample reason for it not being seen on its earthward path. Fesenkov[13] finds that, for all possible cometary orbits calculated from the fireball trajectory, the angular distance between the comet and the Sun is small. When the comet encountered the Earth it would be coming from a point in the dawn sky comparatively close to the Sun and would thus be most difficult to detect and observe. The orbital configuration is similar to Comet Mrkos which was only detected after having rounded the Sun and travelled beyond the Earth's orbit.

It is most difficult to calculate the expected flux of these very small cometary nuclei to the Earth's surface because of the lack of relevant observational data. Vsekhevyatskii[14] gives cumulative number data for comets with $1 < \mathrm{mag}_0 < 14$ A wanton extrapolation of Whipple's[15] interpretation of this data gives a value of 7×10^8 for the number of comets brighter than $\mathrm{mag}_0 = +26$ which pass within 1.2 AU of the Sun within 100 yr. Using Everhart's[16] calculations the chance of such a comet striking the Earth is about 5×10^{-2} in 100 yr; so one on average should hit the Earth every 2,000 yr.

Comparing the ablation and deceleration of the cometary nucleus with that of a meteoroid forming a meteor train it can crudely be assumed that one atom (or molecule) of the incident body is ablated (albeit with a high energy) when it is struck by an atom (or molecule) of the atmosphere. The cometary nucleus thus explodes when it has collided with a mass of air equal to its own mass. Assume that the atmosphere has a density, ρ, at a height h of $\rho = \rho_0 \exp(-h/H)$ where ρ_0 is the density at ground level and H is the scale height (~ 7 km). The cometary nucleus (radius r_c, density ρ_c moving on a trajectory inclined at an angle χ to the vertical will intersect a mass M_c in descending to height h_1, where

$$M_a = \pi r_c^{\,2} \sec\chi\, \rho_0 \int_{h_1}^{\infty} \exp(-h/H)\, \mathrm{d}h \tag{3}$$

M_a is equal to the comet mass $(4\pi\rho_c r_c^{\,3}/3)$ at the explosion height $h_{\bullet}$ given by

$$h_{\bullet} = H \log_e \left(\frac{3 \sec\chi\, \rho_0 H}{4\pi r_o \rho_c} \right) \tag{4}$$

Putting $h_e = 8.5$ km, $H = 7.1$ km, $\rho_0 = 10^{-3}\ \mathrm{g\,cm^{-3}}$, $r_o = 2.1 \times 10^3$ cm and $\rho_c = 1.14\ \mathrm{g\,cm^{-3}}$ gives $\chi = 1.5°$. Fesenkov[13] concluded that χ was between 65° and 70° and probably larger, Levin[10] calculated χ to be 82°. The low value calculated above is probably due to the initial assumption of a one to one ratio between collision atoms and ablated atoms. The formation of an aircap around the nucleus in the lower, denser, regions of the atmosphere will lessen the ablation and enable it to traverse a longer atmospheric path and thus have a higher value of χ.

Magnetite and silicate globules, 80–100 μm in size, were recovered from the soil near the explosion site Detailed analysis of these revealed small amounts of Co and Ni as well as traces of Cu and Ge[17] and this has been offered as partial proof of the 'alien spacecraft' hypothesis. It must be remembered, however, that these elements are most probably present in the dust of the cometary nucleus at their normal cosmic abundances. Their high values of ionisation potential vitiates against them showing up in cometary spectra.

One of the major stumbling blocks of the cometary impact Hypothesis is the ^{14}C anomaly that is said to have occurred in 1909. Cowan *et al.*[6] found that the ^{14}C activity was higher in that year than normal and deviated from the mean by over two standard deviations (but see ref. 18). Cowan *et al.*[6] manufactured this extra radiocarbon in the atmosphere by proposing that 1/7 of the Tunguska energy was due to anti-matter annihilation. Hunt *et al.*[5] produced this ^{14}C excess by a nuclear explosion at Tunguska. A sudden influx of ^{14}C into the Earth's atmosphere will be observed as a positive anomaly in the graph of radioactive CO_2 content as a function of time, this anomaly having a width (to half maximum values) of about 2.4 yr. This is because atmospheric CO_2 is continually being removed by plants in the biosphere, converted to humus and then returned to the atmosphere as this humus decays; 5% is absorbed each year in this way. CO_2 also dissolves into the oceans, rainfall helping considerably, and this removes about 20% yr^{-1} (see ref. 19). So 25% of the atmospheric CO_2 is being locked away each year, remains locked away for between 10 and 50 yr and is subsequently slowly returned by plant decay and oceanic evaporation.

Now, if all the kinetic energy of the comet (5×10^{23} erg) were converted into heating its constituent particles and an equal mass of the atmosphere (mean mass 12) the temperature obtained would be about 2×10^6 K. Since this is substantially sub-nuclear it has been argued that normal cometary impact could not have produced the observed radiocarbon. It is entirely fallacious to suppose that sub-nuclear temperatures cannot produce nuclear effects as can be seen by consideration of the solar flare phenomenon. In a flare, the mean temperature of the particles is certainly less than 2×10^7 K, that is an energy of order 10^{32} erg distributed among some 10^{16} g. Even at the low densities of the solar atmosphere, many associated high energy phenomena are seen to occur—the production of X and γ rays, MeV electrons and GeV nuclei[20]. The mechanism by which these are produced is still not properly understood but qualitatively may be attributed to stochastic acceleration of particles in the turbulent spectrum of plasma waves generated in the flaring atmospheres by the primary energy release. Although this process is magnetohydrodynamic in character the solar magnetic field need not play any direct part (other than as the source of energy) since the large particle velocities and the ionisation produced by any explosion can generate the necessary magnetohydrodynamic conditions. Similar results are, therefore, to be expected in the Earth's atmosphere following a cometary impact.

We can estimate the ^{14}C production in the Tunguska cometary impact by a rough scaling comparison with the flare results, without specifying the detailed process. The collisional production of energetic neutrons by the accelerated particles varies as $nNQV\tau$ where n is the atmosphere number density in the heated atmosphere, N the total number of particles in the heated volume, Q the neutron production cross section, V, the mean particle velocity, and τ the duration of the event. Thus if υ is the number of neutrons produced and the comet and flare characteristics are denoted by subscripts C and F then

$$\upsilon_c = \upsilon_F \frac{n_C N_C Q_C V_C \tau_C}{n_F N_F Q_F V_F \tau_F} \tag{5}$$

From the cometary mass of 5×10^{10} g we have $N_c \simeq 2 \times 10^{33}$ while the atmospheric density at 8.5 km gives $n_c \simeq 2 \times 10^{19}\ \mathrm{cm^{-3}}$ and for a flare $N_F \leq 10^{40}$. The density in the flare acceleration region is uncertain but is probably around $n_F \simeq 10^9\ \mathrm{cm^{-3}}$, and the typical flare duration is $\tau_F = 100$ s. Chupp *et al.*[21] have set an observational upper limit to the number of 20 meV neutrons formed even in a 2B flare as $\upsilon_F \leq 10^{25}$. Thus from equation (5) we have

$$\upsilon_C \simeq 3 \times 10^{26} \left(\frac{Q_F V_C}{Q_F V_F} \right) \tau_0 \tag{6}$$

The factor in parentheses in equation (6) is uncertain because the detailed process of neutron formation is unknown Certainly the typical nuclear collision speed V_c in a cometary impact explosion may be less than that in a flare (V_F) since the explosion temperature driving the plasma process is lower. On the other hand, the neutrons proposed by Cowan *et al.*[6] for radiocarbon formation are only of about 10 MeV energy so Q_C/Q_F may be substantially larger than unity. If, therefore, we estimate the whole parenthetic term in equation (6) as unity then we expect $3 \times 10^{26}\ \tau_C$ neutrons to be formed in a Tunguska-type cometary impact. By comparison Cowan *et al.*[6] estimate that about 10^{27} neutrons are required to explain the radiocarbon data. Thus, if the necessary hot plasma conditions were sustained in the Earth's atmosphere for at least 3 s (a very plausible figure compared with the duration of enduring meteor trails, overdense diffusion times, etc.) then the required neutron formation would probably ensue by non-thermal plasma processes.

We conclude, therefore, that within the uncertainties of the effect of chemical composition on collective plasma acceleration processes and on collisional neutron production, the number of neutrons expected in the Tunguska impact, as scaled from solar flares, is in remarkably good agreement with the radiocarbon data requirements. Also the low mass of the comet (5×10^{10} g) coupled with its extreme faintness ($\text{mag}_0 = +26$), and its position in the dawn sky, just before impact makes its prior discovery extremely unlikely. These points strongly support the suggestion that the Tunguska explosion was caused by an impacting small comet and that nothing more exotic need be invoked.

Antarctic topography from balloons

ANTARCTIC ice surface elevation maps are far from being complete, due to the difficulties in applying regular surveying and mapping techniques in Antarctica. A new wealth of ice sheet surface topography data is now available, from many balloons, floating at an altitude of about 12.5 km, which traversed the Antarctic during its 1975 summer. These balloons were part of 411 constant density balloons launched in the Southern Hemisphere during the Tropical Wind, Energy conversion and Reference Level Experiment (TWERLE)[1]. Each balloon carries three sensors: radio altimeter[2], pressure sensor[3] and ambient temperature sensor. The balloon transmits data once per minute, as long as its solar panel is sufficiently illuminated[4]. The data are received by the Random Access Measuring System (RAMS)[5] on board the NIMBUS-6 satellite, whenever the balloon is within line of sight.

The near Polar orbit of NIMBUS-6, and the continuous summer daylight combined to allow continuous coverage of TWERLE balloons, south of 66°S, during December 1975 and January 1976. Continuous coverage means 13–14 passes per balloon in 24 h. The longest pass is an overhead one, which lasts more than 15 min, hence the data consists of 15 transmissions, or less, per pass. In addition to recording the balloon's sensors data, RAMS also measures the received carrier frequency. The Doppler history of up to 15 transmissions during an overpass yields the balloon position[6]. Two consecutive passes can produce the wind information.

The average balloon life during TWERLE was slightly more than two months, with some balloons lasting more than a year. The launching strategy and the general circulation at balloon height caused a typical daily concentration of about 40 balloons south of 45 °S, during December 1975–January 1976. Many of these ballons traversed the Antarctic Continent.

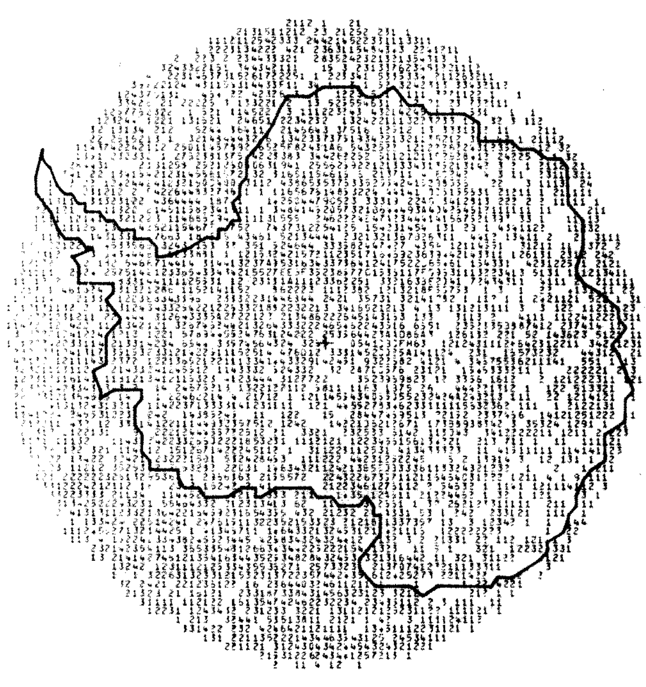

Fig. 1 TWERLE balloons coverage over Antarctica 1 November 1975–19 March 1976. Each symbol indicates the number of measurements over a square 55×55 km (1 = 1,. . . . 0 = 10, A = 11, B = 12,. . . . .). The data boundary corresponds to 65 °S, and 0° longitude is up.

The extent of Antartic coverage by the TWERLE balloons is summarised in Fig. 1. This gives the total coverage from all the balloons during the period 1 November 1975–19 March 1976. Each symbol on the map indicates the total number of measurements over a square of 55×55 km. A measurement is the average of up to 15 balloon transmissions, 1 min apart, recorded during the satellite overpass. As Fig. 1 shows there is almost complete coverage over Antarctica, with many squares being traversed more than once.

The radio altimeter data over Antarctica resembles overwater data, as far as standard deviation of the 15 altitude readings per pass. This small standard deviation is due to the flatness of the ice cover. The ice flatness further contributes to the measurement accuracy by reducing the adverse importance of position error, which is specified at 5 km.

To obtain the surface elevation from the altimeter readings it is necessary to know the balloon's altitude above sea level (a.s.l.). Constant altitude could not be assumed because (1) the altitude of a constant density level is not constant, and (2) the balloon equilibrium density changes following diurnal cycles. What can be assumed constant, for several hours at least, is the altitude a.s.l. of a pressure level along the balloon trajectory. This is the result of the quasi-geostropic nature of the wind. In other words, the balloon, which follows the wind, is moving parallel to the isobars. It can be concluded that the balloon altitude a.s.l. could be calculated if the altitude of a reference pressure surface above the balloon subtrack is known once a day. 150 mbar was chosen as this reference pressure, because it is the standard radiosonde level nearest to the balloon flight level.

The relation between the surface elvation, the altitude of the 150 mbar pressure surface and the altimeter reading is

$$E = Z(150\ \text{mbar}) - (P + P_{\text{corr}} - 150)\,(0.2T + 53.7) + \\ + (75 \cos^2\Phi - 15) - h \qquad (1)$$

where E is the surface elevation a.s.l. in metres, $Z(150\ \text{mbar})$ is the altitude of the 150 mbar surface in geopotential metres, P is the pressure sensor reading in mbar, P_{corr} is the pressure sensor correction in mbar, T is the ambient temperature reading in °C, Φ is the latitude and h is the altimeter reading in metres.

The second term on the right hand side is the altitude difference between the balloon's pressure level and the 150-mbar pressure level, using a linear approximation to the hydrostatic relation. The third term is an approximation to the difference in the balloon altitudes when given in units of geopotential metres and geometric metres. P_{corr} is the difference between true pressure and the pressure sensor reading. Once in altitude, the TWERLE pressure sensor is very stable. Erroneous prelaunch calibration, however, and very long term drift may cause a bias error of up to 3 mbar. This bias error can be removed by several comparisons with 150-mbar synoptic maps, when the balloon flies over water in an area well covered by radiosonde data, such as Australia and New Zealand.

The altitude of the 150-mbar level above the balloon subtrack, for use in equation 1, should also come from radiosonde data. The radiosonde network in Antarctica is, however, too sparse to produce good synoptic maps. To our help come all the other TWERLE balloons in the area. Balloons over water provide both the geopotential height of the pressure surface and the wind. Balloons over land are used for wind only. Figure 2 is one of the synoptic maps drawn for the analysis of a test case balloon no. 766. On that day, there were only nine radiosonde stations south of 45 °S which reported the wind and/or the geopotential height of the 150-mbar level, at the mandatory time of 1200 GMT. There were, however, 32 more TWERLE balloons south of 45 °S reporting the same information.

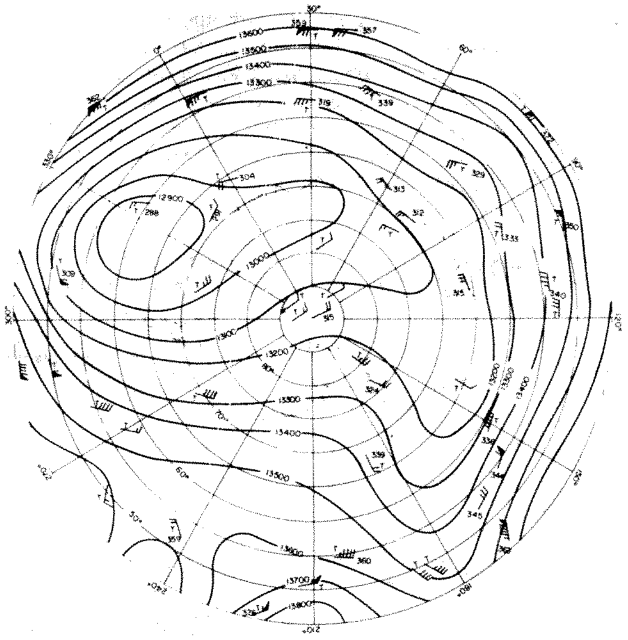

Fig. 2 Synoptic map of the 150 mbar pressure surface at 1200 GMT, 11 December 1975. Constructed from nine radiosonde reports and 32 TWERLE balloons (marked with 'T'). The balloon marked 'X' is no. 766, whose full trajectory appears in Fig. 3.

The first balloon to be analysed during its Antarctic traverse was balloon no. 766. Its trajectory from 3 December 1975 till 14 December 1975 is plotted in Fig. 3. Next to each position, the elevation of the Antarctic continent calculated using Equation 1 is given. P_{corr} for balloon no. 766 was checked six times during the 100 d preceding the traverse, and was found to be 1.7 mbar. Six synoptic maps, similar to Fig. 2, were plotted for the traverse period.

The estimated error budget in the calculated elevation is as follows: pressure surface: ± 30 m, altimeter: ± 10 m, pressure sensor: ± 10 m, position error of 5 km at a slope of 2 m km^{-1}: ± 10 m. Adding all these yields a worst-case error of ± 60 m. This accuracy is comparable to accuracies of ± 30 m obtained during aircraft radio echo soundings[7], and to accuracies of ± 50 m obtained in over-snow traverses using the two barometric altimeters method[8].

There are several absolute check points available for the elevation data in Fig. 3. First there are three measurements of the sea surface elevation before crossing the shore line at the beginning of the traverse. These exhibit a maximum error of 31 m. Then there are the sea surface measurements at the end of the traverse, which exhibit maximum error of 18 m. A relative check is available at the poleward most crossover in the trajectory. On 8 December 1975 an elevation of 2,038 m was obtained when the balloon passed over position 85° 97′S, 324° 25′E. Three days later, an elevation of 2,042 m was obtained for 85° 98′S, 324° 29′E.

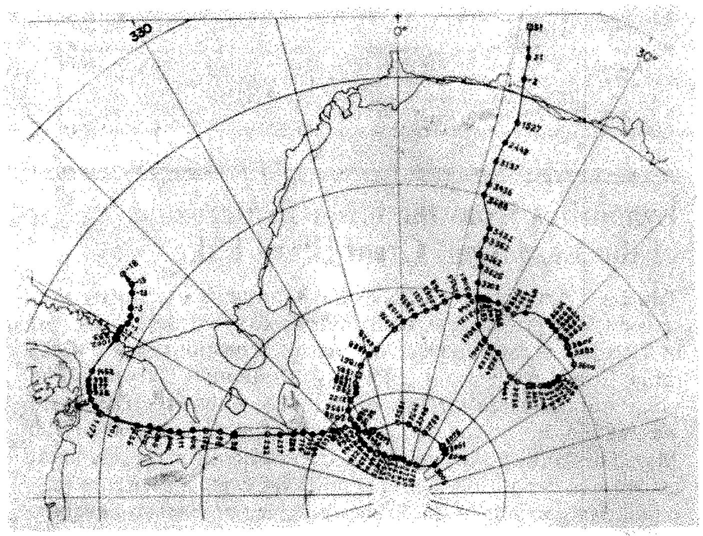

Fig. 3 The traverse of TWERLE balloon no. 766 over Antarctica, 3–14 December 1975. The Antarctic surface elevation at the balloon subtrack was calculated using equation (1), and is given in metres. The first known position on a GMT day is marked by a square.

Another indication of the accuracy is available from a preliminary comparison with the Radio Echo Sounding Map of East Antarctica[7], performed on 33 well distributed localities, measured from five different balloons. The average error was +7 m (balloon data being higher), and the standard deviation of the differences was 36 m. Whenever the balloon subpoint did not coincide with an elevation contour line of the radio echo map, a linear interpolation between the two neighbouring contour lines was used. In five out of the 33 comparisons, the differences were larger than 60 m (the largest being −83 m), however, it should be noted that the sum of the two accuracies is ±90 m. It can be concluded that the accuracy of the data, and the extensive coverage promise significant additions to the Antarctic ice maps. (The data already analysed is available from Nadav Levanon, in tabulated form.)

The information on which this report is based was obtained during the Tropical Wind, Energy Conversion and Reference Level Experiment (TWERLE), supported by NASA and NSF, and administered under a University Corporation for Atmospheric Research contract with NSF. The analysis is supported by the US–Israel Binational Science Foundation.

Evaporites from the lower Proterozoic of the East Arm, Great Slave Lake

THE East Arm of Great Slave Lake contains excellently preserved lower Proterozoic sedimentary rocks that were deposited in fluviatile, coastal and shallow marine conditions. These rocks range in age from about 2,400 Myr to about 1,600 Myr. The polar wander curve for this period[1] shows that the East Arm was within 30° of the equator during the period 1,900–1,700 Myr. The sediments deposited during this period show abundant evidence of deposition in arid conditions, especially in that they contain indications of the former presence of extensive evaporites. Evidence of former evaporites is lacking in those sequences deposited apparently beyond 30° from the palaeoequator. Permian to modern marine evaporites are generally confined to ±30° of latitude. It is proposed, therefore, that climatic (and by possibly atmospheric and hydrospheric) conditions were grossly similar in the lower Proterozoic to those of today. These deposits pre-date similar sequences in the MacArthur River area by some 300 Myr (ref. 2). They predate the supposed initiation of sulphate evaporites by 1,000 Myr (ref. 3) and clearly negate Cloud's various hypotheses about the evolution of the Earth's atmosphere and hydrosphere.

The East Arm of Great Slave Lake is a graben within which there was intermittent sedimentation and igneous activity from 2,500 Myr ago to 1,300 Myr ago[4]. Three major groups have been defined[5]. (1) The Wilson Island Group. A group of shallow water sedimentary rocks and volcanics older than 2,200 Myr; (2) The Great Slave Supergroup, deposited between about 2,200 Myr and 1,790 Myr; (3) The Et-Then Group, deposited between ~ 1,700 Myr and 1,600 Myr.

The Wilson Island Group has been metamorphosed and deformed, although locally there are well preserved, unmetamorphosed sections. The other groups are unmetamorphosed and beautifully preserved. Throughout much of the lower Proterozoic deposition was in shallow water and fluviatile, tidal-flat and shallow marine sediments are abundant (Table 1).

The polar wander path for North America[1] indicates that the East Arm within 30° of the equator during the deposition of the middle and late Great Slave Supergroup (from about 1,900 Myr to about 1,700 Myr). The bulk of Permian-modern marine evaporites has been essentially confined to ±30° of latitude[6]. The depositional environments in the East Arm indicate that ideal conditions for evaporite formation were frequent. The palaeomagnetic data indicate that we could expect evaporites in the sequence between 1,900 Myr ago and 1,700 Myr ago. In Table 1, we show those formations that contain evidence for evaporites and we document the evidence below.

The oldest unit in which there is evidence for evaporites is the Kluziai Formation. In the Snowdrift area, there are nodules of slightly ferroan dolomite within fine-grained, well-sorted sandstones. The nodules are usually restricted to certain horizons. They are 1–2.5 cm in diameter and usually consist of a single poikilotopic dolomite crystal. Similar nodules occur in the top of the Hornby Channel Formation in the same area but are not well preserved. The nodules are similar to ones found in the Zambian Copperbelt sandstones, and Annels[7] has shown how carbonate has replaced plates of anhydrite and gypsum which are still preserved in places in these rocks. It is proposed that the nodules in the Kluziai Formation have replaced original anhydrite.

Additional evidence for evaporites in the Sosan Group comes from the Akaitcho River Formation on Seton Island where

Table 1 Evidence for the presence of evaporites in the East Arm, Great Slave Lake

		Group	Formation	Lithology	Deposition environment	Evidence for evaporites
	1200					
		Et-Then	Preble	Sandstones	Fluviatile	
			Murky	Conglomerates	Alluvial Fan	
Great Slave Supergroup	1795	Diorite Intrusion

		Union Island		Basic volcanics, Dolomites and Red and black shales	Shallow marine	
		Wilson Island		Volcanics, Quartzites, Dolomites and siltstones		
	>2485	Basement				

Olade and Morton[8] described pseudomorphs after gypsum from red siltstones and shales. These sediments are overlain by volcanics of the Seton Formation, which have been dated on Seton Island at 1,872 Myr (ref. 9). In the Akaitcho River Formation at Reliance, there are small (0.5 mm) nodules of length slow chalcedony (quartzine), which may indicate replaced evaporites[10]. It is interesting that these occur in well-sorted glauconitic sandstones. The glauconite occurs as pellets which have cracks infilled with carbonate—a feature that has been ascribed to desiccation[11]. In these two areas, the Formation was deposited in shallow marine, perhaps intertidal conditions. On the north shore, at Talthelei Narrows, red mudstones of the Akaitcho River Formation contain beds with haematite pellets and carbonate nodules as well as casts after gypsum. These beds are interpreted as pedogenic horizons and probably were formed in a sabkha environment.

Pseudomorphs after gypsum are also common in the Kahochella Group. They occur in the upper parts of the Gibralter Formation in intertidal red mudstones with stromatolites, intraformational conglomerates and pelletoid ironstones[12]. Casts after gypsum have been described from tuffs of the Seton Formation, again associated with pedogenic horizons, and from red shales with carbonate concretions in the McLeod Formation near Reliance. The Douglas Peninsula Formation contains similar casts in red fissile mudstones with carbonate or haematite/jasper laminae. Hoffman[12] has tentatively proposed a lacustrine origin for these rocks which probably formed in a sabkha environment. During the remaining Pethei Group times shallow-water sediments were only deposited on a northern platform. Of the platformal sequences, the Utsingi Formation of stromatolitic limestones and dolomites has been tentatively described as a supratidal sabkha deposit[12]. We have observed evaporite breccia and contorted laminae within the unit at Reliance. Both features resemble closely those in the Purbeck Formation of Dorset, where the latter has been cited as part of the evidence for the former presence of evaporites[13].

On Isui Island, there is a sequence of fissile, red, calcareous mudstones containing thin laminae of red-stained carbonate and calcite pseudomorphs after anhydrite. The sequence is in fault contact with other units, but closely resembles the Douglas Peninsula Formation with which it is tentatively correlated[17]. The laminae are disturbed by small scale cross-lamination and scours, but also by crinkle folds (1 cm amplitude) which probably formed while the rock was still plastic. There are plugs of brecciated, banded drusy calcite up to 3 m across cutting these sediments. The plugs contain clasts of red dolomitic mudstone. Plugs of oligomictic breccia with no calcite cement are also seen to cross-cut bedding. The drusy calcite contains streaky layers of red calcareous mudstone. Rosettes and euhedral crystals of barite occur in bands in these layers of calcareous mudstone and overgrow the drusy calcite. These features closely resemble the upper zone of the cap rock of a salt dome[14] except that they are on a far smaller scale. They are, however, also similar to structures produced by small scale movements over anhydrite beds[15]. There is no evidence for halite in nearby rocks, but pseudomorphs after anhydrite are abundant. We, therefore, suggest that these plugs were perturbations in the top of an anhydrite bed that has subsequently been calcitised.

In Christie Bay Group times, the polarity of platform and basin broke down, and once again shallow marine to arid coastal conditions prevailed over much of the East Arm. The best evidence of former evaporites comes from the Stark Formation which consists of dolomites, red mudstones and siltstones. Stromatolite mounds, crinkled algal laminae, flat pebble conglomerates, wave ripple marks, and loading and shrinkage cracks all point to an intertidal to supratidal origin[12,16]. The laminated dolomites are often highly brecciated, and there are various types of breccia. In places, almost the entire thickness of the formation (in excess of 1,000 feet) is disrupted to a megabreccia. Elsewhere small patches of breccia occur amidst undisturbed strata. The breccias were attributed to gravity tectonics around rising diorite laccoliths,[4,12] an hypothesis rejected by Badham[18] who proposed that they were analogous to evaporite breccias elsewhere and the result of collapse after solution of evaporites. More recently Hoffman *et al.*[19] have concurred with this view and have proposed an elegant model.

The Stark Formation retains evidence, other than the breccias, for the former presence of evaporites. The dolomites contain vugs wholly or partially filled with ferroan dolomite and younger calcite. The vugs are up to 2.5 cm long and compaction has occurred around them. They are confined to pyritic, stromatolitic dolomite and are most common in the base of algal mounds. They disrupt original laminae and are associated with shrinkage cracks. The association is similar to that in the Middle Jurassic of Scotland[2]. The vugs are similar to the elongate fenestrae of the medium laminoid fenestral fabric and are assumed to have once contained gypsum[21]. The red mudstones contain abundant and well developed pseudomorphs after halite. These are now usually filled with dolomite, but in the aureoles of the diorite laccoliths feldspar is the replacing mineral. It is suggested that the Stark formation originally contained thick sequences of evaporites, most of which were removed in solution with concomitant collapse of overlying strata. Some of the breccias and deformation within the Upper Christie Bay Group may, however, be due to salt diapirism—a hypothesis which needs more detailed investigation.

The youngest evaporites in the East Arm occur in the Portage Inlet Formation. Pseudomorphs after halite are common in buff sandstones and shales, which commonly also contain desiccation cracks. Mudstones at the top of the Formation contain pseudomorphs after rosettes and single crystals of gypsum[12].

There is, therefore, abundant evidence for evaporites in the middle and late Great Slave Supergroup. Much, but by no means all, of this evidence is from pseudomorphs after gypsum. Gypsum may also form during the degradation of sulphides[22]. The nature of the sediments and the other evidence of evaporites suggest, however, that the gypsum was of evaporitic origin. Many of the East Arm evaporites were deposited on supratidal flats and sabkhas, an environment where similar sediments with evaporites are forming today. Evidence for former evaporites is found only in the middle and late Great Slave Supergroup and not in the Union Island and Lower Sosan Groups, when equally suitable depositional environments existed. This suggests that (1) the distribution of lower Proterozoic climatic belts (and thence the geographic distribution of evaporites) was broadly similar to that of today and (2) the palaeomagnetic data are correct.

Finally it is interesting to note evidence for the former presence of evaporites from rocks of the Belcher Group (in Hudson Bay) of similar age to the Upper Great Slave Supergroup[23]. This evidence supports the above conclusions.

We thank D.I.A.N.D., Yellowknife, Rio Algom Ltd, Vestor Explorations Ltd and N.E.R.C. for logistic and financial support. We also thank Ian West and Ernie Hailwood for valuable discussions and criticism.

Polycyclic aromatic hydrocarbons in long-range transported aerosols

THE presence in Norway of long-range transported air pollutants from the European continent and England is well established. In particular, SO_2 and other inorganic compounds in precipitation have been studied[1]. Less attention has been paid to the organic constituents of the long-range transported pollutants. Several organic components have been identified in precipitation in Norway[2], including alkanes, polycyclic aromatic hydrocarbons (PAH), phtalic acid esters, fatty acid esters, fatty acids, and dicarboxylic acids. In addition some chemicals typically connected to industry and industrial products are present. Long-range transfer of PAH compounds, in particular, is of environmental interest since a number of such compounds cause cancer in animals and they are also suspected to be human carcinogens[3]. We report here preliminary results on the PAH-content of long-range transported and stationary air masses.

All samples were taken by the Norwegian Institute for Air Research at their sampling station at Birkenes in southern Norway. Airborne aerosols were collected by high-volume samplers on glassfibre filters. About 2,500 m^3 air was drawn through the filters per day, and the filters were changed every 24 h. The origin of the air masses transferring the pollutants has been indicated by trajectories which are calculated on the basis of meteorological data[4]. When the trajectories showed that consecutive filters were sampling air of the same origin, the filters were combined before analysis.

The air filters reported in this work represent two sets. The first set contains samples of air which had come from France/England (sample 1) and England/Scotland (sample 2). The other set contains samples of air coming from northern Norway (sample 3) or of stationary air from southern Norway (sample 4). The samples represent air sampled for 24, 48 and 72 h.

The analytical procedure used in this work is based on the method of Grimmer and Böhnke[5]. Gas chromatographic analysis was performed using a Carlo Erba Fractovap 2101 A gas chromatograph equipped with a 50 m × 0.34 mm i.d. glass capillary column coated with OV 1. The technique of splitless injection of the sample was used[6]. Retention times and peak areas were registered automatically by means of an electronic integrator. The PAH compounds were identified by comparing the chromatograms with those of the PAH-standards and the amounts were determined comparing the electronically integrated areas of each peak with those of the internal standards.

Results of the PAH analyses are given in Table 1 and a typical gas chromatogram is shown in Fig. 1. It is seen from the chromatogram that the system used is capable of separating critical isomers such as benzo(*a*)pyrene from benzo(*e*)pyrene and benzo(*a*)anthracene from chrysene and triphenylene. This separation is essential for characterising the potentially hazardous PAH components in environmental samples.

Table 1 shows that 20 different PAH compounds have been identified and determined. These include some of those reported to be carcinogenic[3]. It is also shown that the samples from western Europe contain about 20 times more PAH than the samples from northern Norway and the stationary air from southern Norway. Although these samples are taken over short periods only, and are not neces-

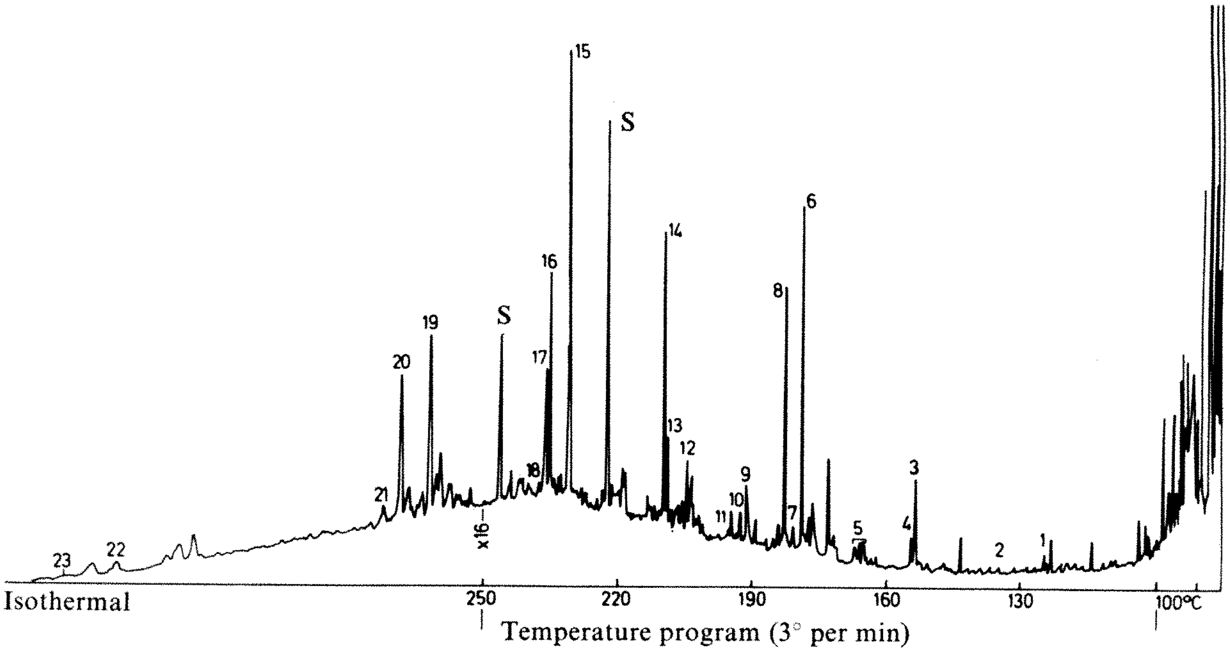

Fig. 1 Gas chromatogram of air filter sample originating from northern England and Scotland. The combined air filters were extracted with 50 ml cyclohexane for 16 h in a Soxhlet apparatus. Before extraction two internal standards, β′β′-binaphtyl and *m*-quaterphenyl, were added. The solution was then extracted with 50 ml dimethylformamide (DMF)/water(9:1). The extraction was repeated with 25 ml of the DMF–water solution. 100 ml water were added to the combined DMF–water solutions and subsequently extracted twice with a total of 75 ml cyclohexane. The cyclohexane-solution was washed twice with distilled water, dried with Na_2SO_4, and concentrated to about 10 ml on a modified Kuderna–Danish apparatus under reduced pressure. The extract was further concentrated to about 0.5 ml on a heatblock (30 °C) under a gentle stream of highly purified nitrogen. The peak numbers refer to the numbers in Table 1. The main components are (3), phenanthrene; (4), anthracene; (6), fluoranthene; (8), pyrene; (15), benzo (*b*&*k*) fluoranthene; (16), benzo(*e*) pyrene; (17) benzo(*a*)pyrene; (18), *o*-phenylenepyrene; and (19), benzo(*ghi*)perylene. S, Internal standards.

sarily representative of air that has travelled from England, the concentrations of benzo(*a*)pyrene and some other PAH's are of the same order of magnitude as the mean values reported in recent years in London[7]. The results of this study, though preliminary, show clearly the presence of PAH in atmospheric long-range transported aerosols. Studies have now been extended to incorporate further samples and other sampling stations.

We thank the Norwegian Institute for Air Research for providing air samples and, in cooperation with the Norwegian Institute for Meteorology, for calculating the trajectories. We thank Mr B. Olufsen for assistance in analysing the air filters.

The microbe thermistor

We describe here the development of a new analytical configuration, called a microbe thermistor, in which immobilised micro-organisms are placed in proximity to a thermistor which measures the metabolic heat evolved by them. Many metabolites can thus be analysed, as we show here by the determination of both single components such as glucose and fructose and of more complex mixtures such as casein. This is in contrast to other analytical applications of immobilised enzymes, for example enzyme electrodes[1–3] and enzyme thermistors[4–6], which can normally allow analysis of only one compound at a time.

We used immobilised whole cells such as *Saccharomyces cerevisiae*, baker's yeast, as a broad specificity sensor. To take full advantage of the generality of such a microbial sensor, a thermistor was chosen as the most suitable transducer, since practically all reactions catalysed by the enzymes of a micro-organism are, in the right conditions, accompanied by temperature changes which can be registered by a thermistor. This is in marked contrast to the situation with bioelectrodes, where the electrode entity can only partly match the 'output' from the sensor because of its specificity for only one or a few different molecular species.

The yeast cells were immobilised in 15% polyacrylamide[7] as follows: Washed baker's yeast cells (5 g wet weight) were suspended in 5 ml of ice-cold water, and mixed with 10 ml ice-cold freshly prepared monomer solution in 0.2 M potassium phosphate buffer, *p*H 7.0, containing 2.85 g acrylamide, 0.15 g *N*,*N*′-methylene-*bis*-acrylamide, 20 µl tetramethylethylenediamine and 10 mg ammonium persulphate. The mixture was immediately poured on to a glass plate provided with stainless steel spacers (0.7 mm), and another glass plate was placed on top of the liquid pool, thus forcing the suspension to form a layer 0.7 mm thick. Polymerisation started within 1 min and was considered complete after 1 h. The gel sheet obtained was passed through a stainless steel mesh giving gel grains of cubic shape, approximately 0.7 × 0.7 × 0.7 mm. Fines were decanted and the yeast-containing grains were finally washed in phosphate buffer for at least 5 h.

To test whether the yeast cells were viable after entrapment in polyacrylamide, the gel grains were disrupted mechanically using a spatula, and the released cells suspended in sterile water, counted under the microscope and spread on malt extract agar plates. Colony counting after incubation for 24 and 72 h at 30 °C revealed that approximately 6% and 8%, respectively, of the released cells had formed colonies. We conclude, therefore, that the entrapment leaves viable cells. It should also be realised, however, that non-viable cells contain several active enzymes[8] and will therefore contribute to the heat formed in an operating microbe thermistor. The reduced viability of the entrapped cells was shown to be due to the toxicity of the monomers (15 min exposure of yeast cells to 15% monomer solution reduced the viability to 3%).

The microbe thermistor was identical to the enzyme thermistor unit described earlier[4]. Approximately 1 g of yeast gel grains were packed in an insulated glass column (0.6 × 4 cm) provided with a thermistor at its outlet. The solution to be analysed was pumped (0.7 ml min^{-1}) through a heat exchanger in an ultra-stable thermostatically controlled water-bath (27 °C) and then through the column. Any heat change occurring in the gel bed alters the resistance of the thermistor and thus gives a signal ultimately registered on a chart recorder (a change in the thermistor temperature of 0.02 °C gave a 100-mV change in the output signal at the highest amplification).

Some basic properties of the enzyme thermistor were deter-

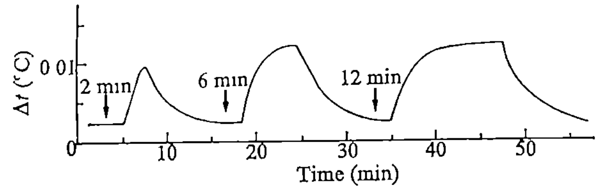

Fig. 1 Experimental curves obtained after injection of 1 mM glucose pulses (in 0.1 M potassium phosphate *p*H 7.0) of varying durations. Arrows indicate substrate introduction.

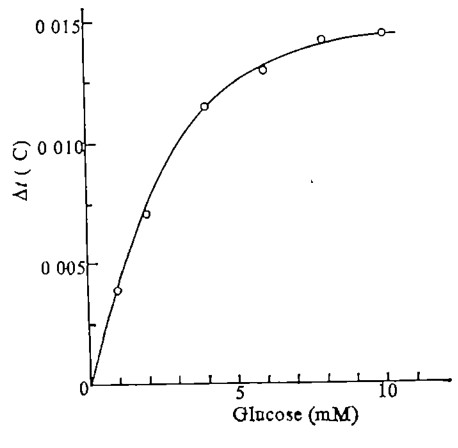
mined with glucose as substrate. Typical response curves shown in Fig. 1 are qualitatively quite similar to those observed with enzyme thermistors. On increasing the pulse length, an increased heat response was obtained until a constant level of heat production was reached. The correlation between heat production and glucose concentration (Fig. 2) is almost linear at low glucose concentrations, but at 10 mM and higher substrate concentrations a typical saturation behaviour is seen.

The microbe thermistor is thus of value for continuous analysis, but in its present state of development it cannot compete with enzyme electrodes, for example, with respect to speed of analysis. A faster response could probably be achieved by lowering the substrate/product diffusion time through the gel using surface-bound microbes and by increasing the substrate turnover choosing other microorganisms with higher metabolic activity. As expected, the microbe thermistor also proved to be sensitive to other compounds, although the response varied with the compound under study. Fructose (in 0.1 M potassium phosphate, *p*H 7.0) gave a heat signal approximately 60% of that found with an equal concentration of glucose, as well as a slower response and a faster decline back to the baseline. The high molecular weight substrate casein (1% in 0.1 M potassium phosphate buffer, *p*H 7.0) also gave a good response (Δt = 0.014 °C) but with a pronounced lag period before a steady-state level was reached. If, however, the casein was predegraded with Pronase, then a faster response was obtained, but with an unaltered final amplitude (measured after 30 min). The rate in the initial period was about twice as high in this case. Thus the entrapped cells can only degrade high molecular weight compounds with difficulty. The same phenomenon, but even more pronounced, was observed using 1% amylose, which gave no heat signal unless pretreated with amylase (batch- or in line enzyme column-wise). After hydrolysis the response was as fast as shown in Fig. 1. The model system studied here thus allows a differentiation between low and high molecular weight sugars. The preparations of entrapped yeast cells were stable for at least one month at 4 °C and for about 7 d during continuous operating conditions, after which time clogging occurred.

Fig. 2 Measured peak height (Δt °C) as a function of glucose concentration. The glucose substrate was dissolved in 0.1 M potassium phosphate and injected as 1-min pulses.



In another set of experiments, the sensitivity to various inhibitors was analysed (Fig. 3). Thus, on adding 2,4-dinitrophenol (1 mM) to the 1 mM glucose solution, an increased heat response was observed (+20%).This may be interpreted as a result of the uncoupling of the oxidative phosphorylation, preventing conservation of metabolic energy (ATP) which in turn leads to an increased heat production. These results are analogous to the findings reported when dinitrophenol was added to a culture of the microalga *Scenedesmus*, being pumped continuously through a conventional flow microcalorimeter[9,10]. On the other hand, 2 mM arsenate (which is known to influence the glyceraldehyde-3-phosphate dehydrogenase catalysed step) decreased the observed heat production from 1 mM glucose, as seen in Fig. 3.

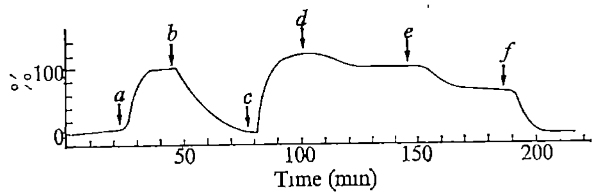


Fig. 3 Thermogram obtained with the microbe thermistor following introduction of various metabolites and inhibitors dissolved in 0.1 M potassium phosphate buffer *p*H 7.0 into the flow. The arrows indicate addition of *a*, 1 mM glucose; *b*, buffer; *c*, 1 mM glucose+1 mM 2,4-dinitrophenol; *d*, 1 mM glucose; *e*, 1 mM glucose+2 mM arsenate; *f*, buffer. The steady-state response to 1 mM glucose is set as 100%.

The use of immobilised microorganisms in combination with suitable transducers offers a flexible alternative of great potential for the analysis of particularly complex solutions. Other organisms or alternative immobilisation techniques could be used in the microbe thermistor. In conclusion, the studies discussed here with the simple microbe thermistor device suggest the following potential areas for its application: (1) its use in analytical determinations of various single components (glucose, fructose) or of more complex solutions (casein); (2) its use in biochemical and microbiological studies, since it conveniently allows successive additions of, for instance, metabolic inhibitors (DNP) or media to the immobilised microbial preparation present in the flow system; and (3) it should also be useful in environmental and process control, as a general indicator for any compound that may affect the metabolism of the microorganism.

Interspecific competition between great and blue tit

Although competition theory predicts that two species can coexist if intraspecific competition, between members of each species, is more important than interspecific competition, between members of different species, or if $\alpha < K_1/K_2$ and $\beta < K_2/K_1$ (with α and β competition coefficients and K_1 and K_2 carrying capacities for species 1 and 2), there were no animal field studies where these predictions are borne out. This letter, however, explains how two closely related titmice, although competing for food during the breeding season, coexist in broad leaved woods.

The great tit *Parus major* and the blue tit *Parus caeruleus* are two sympatric hole nesting passerines with deciduous forest as their optimal habitat. In winter, they consume different foods but during the breeding season they feed to a large extent on the same[1–4]. Kluyver[5] has, therefore, suggested twice that interspecific competition between the two tits might occur, but he provided no evidence for this. British authors[2–4,6] on the other hand, have explained that this food niche overlap is possible because food would be superabundant during the breeding season and therefore competion would not occur. The data from the Ghent study (Table 1) show that great tit reproduction is significantly reduced both by higher great tit and by higher blue tit numbers. This is the result of a reduction of first brood clutches (strong intra-, weak interspecific effect), of an increase in nest mortality (strong intra-, strong interspecific effect), and of a reduction in the proportion of birds undertaking a second brood (strong intra-, and strong interspecific effect).Thus fewer young are produced per pair and per season (very strong intra- and very strong interspecific effect). Blue tit reproduction is affected in a similar fashion but the effect of the great tit is much less pronounced and is only statistically significant on nest mortality.

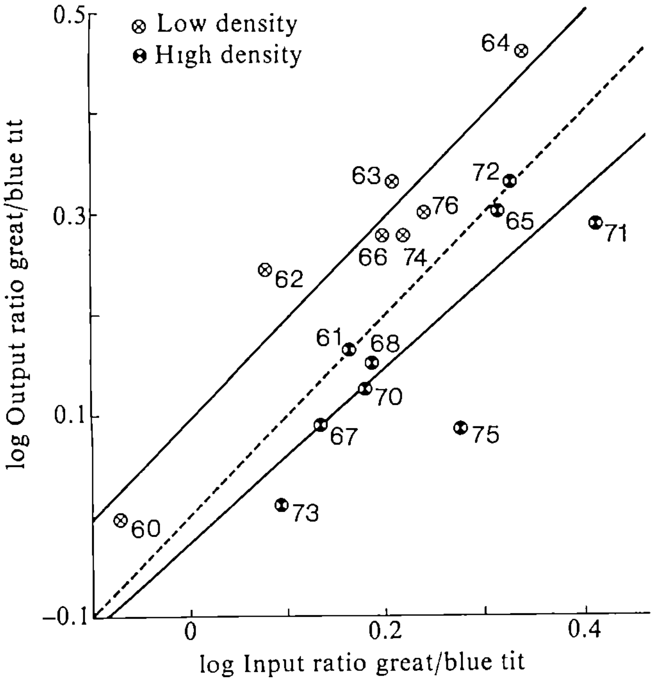

Fig. 1 In plant ecology, Dewit's experimental set up is used to compare the relative competitive ability of two species in different circumstances and at varying relative frequencies, but at the same combined density[7]. If the regression of log input ratio (here log density great tit/density blue tit) against log output ratio (here log number of young fledged great tit/blue tit) lies above the line with slope one through the origin, the species in the numerator does relatively better than the species in the denominator. If the regression line lies below this reference line the reverse is true. As this technique relies on experiments with the same combined density, I selected 7 yr with low combined densities (17–25.8 pairs per 10 hectares, open symbols), and 9 yr with high combined densities (28 1–33 pairs per 10 hectares, partly filled symbols). The low density line lies above, the high density line lies below the line with slope 1 through the origin (stippled), and their slopes are not significantly different from 1 (low density line: slope 1.01, $s_b = 0.14$; high density line slope 0.87, $s_b = 0.22$). This means that the relative frequency does not, but the combined density does affect the relative competitive ability of the tits.

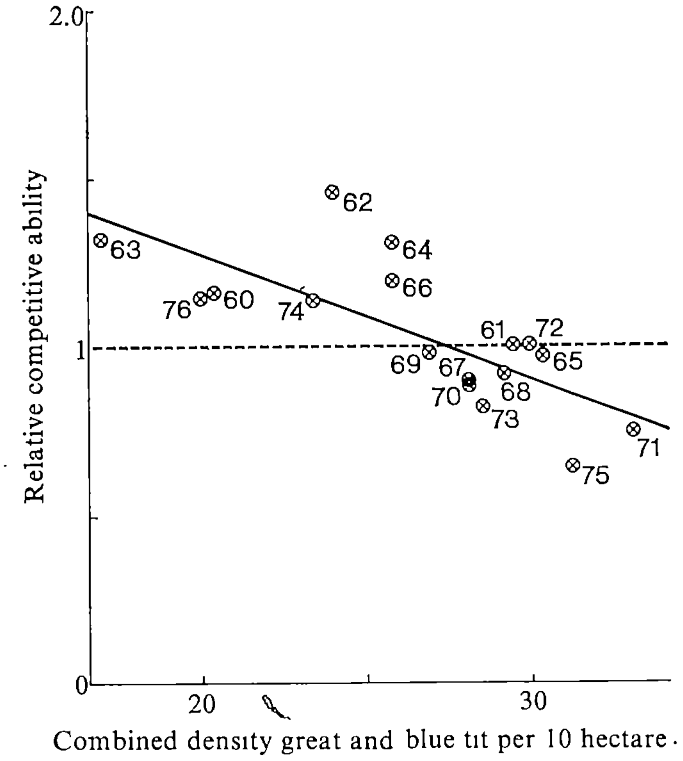

Fig. 2 In Fig. 1, the years were grouped according to low or high combined density but since in this field study densities were not controlled this approach might be criticised. Because combined density seemed to be the factor determining which species will produce relatively more young, the relative competitive ability (ratio of great tit over blue tit density divided by ratio of great tit over blue tit total number of young fledged) is plotted against combined density. The correlation coefficient is highly significant ($r = -0.75$, $F_{1,15} = 19.18$, $P < 0.001$), confirming that the relative competitive ability is dependent on combined density.

All these effects can be related to food. When less food is available per bird, because more birds of either species are present, clutches will be smaller, nest mortality will be higher and it will be more difficult for the females to make up for the weight losses incurred while raising their first brood and thus harder to start a second clutch. Although it could be argued that interference between the birds would have the same result this seems unlikely since (1) there are no observations to support that intra- or interspecific interactions are numerous during the nesting period and especially not when young are being raised (tits being highly territorial species), and (2) the effect of the larger great tit on the smaller blue tit should be more pronounced than vice versa, while in fact the opposite is the case.

Therefore, these negative effects of numbers on reproductive parameters are the result of intra- and interspecific competition for food of the scramble or exploitation type, rather than a possible result of interference competition. This leads to the conclusion that food cannot be superabundantly available during the breeding season.

Why then does the smaller and less numerous blue tit have a stronger effect on the larger and more numerous great tit, than the other way round? To explain this, I hypothesise that the niche of the great tit during the breeding season must be narrower and be contained to a large extent in the broader

Table 1 Intra- and interspecific effect on several reproductive parameters of great and blue tit

The Ghent study was started by J. Hublé in 1959 and is at present supervised by R. Eyckerman. The data used are the weighted averages over the period 1960–1976, from the two best study areas in use since the beginning of the project—Zevergem, an oak wood of 16 hectares (13 hectares until 1963) with 65 nestboxes per 10 hectares, and Maaltepark, a mixed deciduous park of 10 hectares with 78 nestboxes (more details on the study areas in ref. 11). Thus nestboxes were always well in excess. Breeding parameters were determined from weekly controls of all nestboxes throughout the breeding season. Density is the number of breeding pairs per 10 hectares; mean clutch size is calculated from all complete clutches; fertility is the mean number of eggs laid per pair per season, including incomplete, repeat and second clutches; nest success is the proportion of eggs giving rise to fledged young; productivity is the mean number of young fledged from all nests per pair and per season. In our study areas nearly all great and blue tit pairs use nestboxes for breeding (personal observation, personal communication R. Eyckerman)[11].

$^{\circ}P < 0.05$ $^{*}P < 0.025$ $^{*\circ}P < 0.01$ $^{**}P < 0.005$ $^{***}P < 0.001$ (one-tailed test).

feeding niche of the blue tit. The detailed observations in English deciduous forests seem to confirm this hypothesis: Gibb[3] noted that during the breeding season blue tits feed to a large extent on twigs and buds, whereas the heavier great tit uses stouter parts of the tree. These are also used by the blue tit. Betts[4] showed that Lepidoptera larvae, in May, make up the bulk of the food for both species: 84% for the great tit and 56% for the blue tit. 41% of blue tit food (Lepidoptera pupae and Coccidae) is not taken by the great tit (and inaccessible?) whereas only 7% of the great tit diet (adult Coleoptera) is not taken by the blue tit.

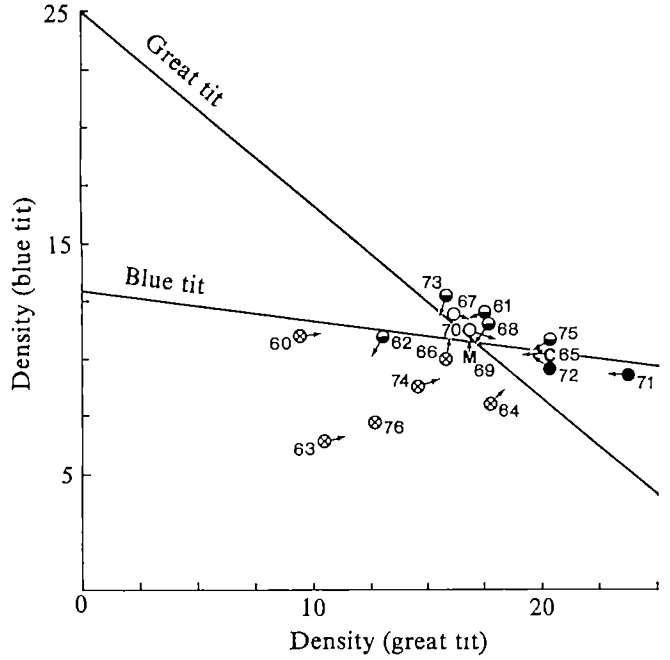

Fig. 3 Equilibrium lines for each species were estimated by requesting eight colleagues to fit the best line for each species so that the points showing an increase until the next year would be below it, the points showing no change on it, and the other points above it. The lines drawn are the averages of these estimates. Although the equilibrium lines varied, in all cases they intersected in such a way that a stable equilibrium would be obtained. The point for 1962 was disregarded because the winter 1962/63 was extremely cold and mortality, especially of the juveniles, was unusually high. The intersections of the equilibrium lines with the axes give: for the great tit $K_1 = 30$, $K_1/\alpha = 25$, and $\alpha = 1.2$; for the blue tit $K_2 = 13$, $K_2/\beta = 100$, and $\beta = 0.13$. ⊗, both species increase; O, both species decrease; ●, blue tit increases, great tit decreases; ◓, great tit increases, blue tit decreases; M: great tit unchanged, blue tit increases; C: blue tit unchanged, great tit decreases.

This way, when it becomes scarce food unaccessible to great tits is still available for blue tits. It is thus shared with fewer competitors and will last longer.

The question that remains is how these two competing titmice coexist in the same preferred habitat. Dewit has shown that two plant species can coexist if the rarer species always has the competitive advantage[7]. Figure 1 shows, using an adapted version of Dewit's method, that the ratio of great versus blue tit numbers does not alter their competitive ability. However, at low combined densities the great tit has the competitive advantage, whereas at high combined densities the blue tit does better, and produces relatively more young. This suggests that the main factor influencing their relative competitive ability would be combined density. This is confirmed in Fig. 2. At a combined density of 27.5 pairs per 10 hectares the relative competitive ability is one and neither species has the advantage. At lower combined densities the great tit produces proportionally more young that the blue tit and at higher combined densities the reverse is true. As long as combined density fluctuates sufficiently both species will coexist. Since great tit numbers vary more than blue tit numbers this will probably result in a stable equilibrium: at low combined densities, great tit numbers will be small and they will increase more than blue tit numbers; this will result in high combined densities and great tits will decrease more than blue tits.

However, it is better to try and estimate competition coefficients and K-values. This is done in Fig. 3 and yields: $\alpha = 1.2$, $K_1 = 30$; $\beta = 0.13$, $K_2 = 13$ (1 = great tit, 2 = blue tit). Thus the effect of the blue tit on the great tit is much larger than vice versa confirming the result obtained in Table 1. The necessary conditions for a stable equilibrium are met since $1.2 < 30/13 = 2.3$, and $0.13 < 13/30 = 0.43$. This means that for both species intraspecific competition is more important than interspecific competition and that, therefore, the great and blue tit can coexist. The stable equilibrium point is at 17 pairs of great tit and 10.5 pairs of blue tit per 10 hectares. Remarkably, this gives a combined density of 27.5 pairs per 10 hectares, which was the stable equilibrium point found in Fig. 2. I suggest that intraspecific competition is mainly for space, as both species are known to be highly territorial and it has been shown that breeding numbers in optimal habitats, for the great tit at least, are limited through territorial behaviour (in spring and in autumn)[8–10], whereas interspecific competition is mainly for food during the breeding season.

I thank R. De Waele, P. Bekaert and F. Fierens for assistance, R. Eyckerman and I. Impens for discussions. Part of this work was supported by the Belgisch Nationaal Fonds voor Wetenschappelijk Onderzoek.

Cercal ablation modifies tethered flight behaviour of cockroach

ANALYSES of insect flight demonstrate a central rhythmic programme modified by means of cephalic and thoracic receptors to allow steering and power output adjustments[1–3]. In orthopteran insects, cercal receptors have never been implicated in flight control, although consideration of their function in cockroaches as directional air current detectors[4] makes this rather surprising. I report here that removal or inactivation of one cercus in a tethered flying cockroach leads to asymmetrical wing movements during flight. Removal of both cerci causes inactivation of forewings and symmetrical beating of both hind wings at a reduced angle to the abdomen. These results suggest cockroach cerci function as specialised equilibrium organs and may relate to the function of cercal interneurones perhaps including the well studied giant fibres (for which there is now no suggested function[5]).

The proterga of unanaesthetised cockroaches (*Periplaneta americana*) were attached by sealing wax to an orthogonal system of three threads which were each further attached to the metal spring of a resistive strain gauge transducer. This allowed limited translation and rotation of the cockroach in three dimensions (Fig. 1). Flight is a complicated behaviour pattern, but for the purposes of this report it is sufficient to describe the approximate angles of the wings with respect to the body and the occurrence or non-occurrence of rhythmic beating. It is unnecessary to present detailed strain gauge measurements. All angles are measured clockwise relative to the median saggital plane of the suspended cockroach seen in frontal view.

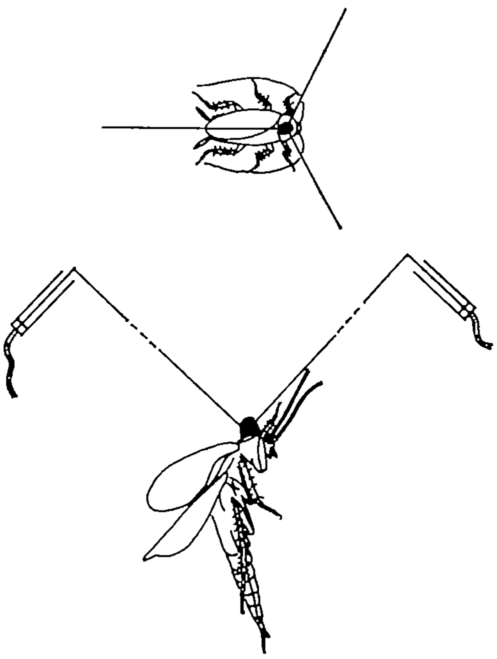

Fig. 1 Dorsal and lateral diagrammatic views of cockroaches suspended by threads from the springs of strain gauge transducers arranged orthogonally. Not to scale.

Suspended cockroaches would fly spontaneously, or could be made to fly by a short puff of air to the head; by making and then breaking tarsal contact with, for example, a finger, or by forced oscillation of the supporting threads. They would often fly for 2 or 3 min. Only one out of 13 cockroaches used did not fly well. After ether anaesthesia in early experiments, cockroaches required 3 d for recovery before they flew well. In normal symmetrical flight (Fig. 2*a*), forewings are held at approximate angles of 90° and 270° for right and left wings respectively and oscillated rhythmically. Hind wings are held at angles of about 120° or 240° and also oscillated. If the threads are asymmetrically fixed to the protergum, so that the cockroach is suspended asymmetrically then the wings on the down-tilted side are held out and oscillated for a longer time than the wings on the other side, and the down-tilted side forewing tends to remain out after all wing oscillation has stopped. If weak flight is initiated, the wings on the uptilted side are not used. If stronger flight is initiated, all four wings are extended and oscillated, but the hind wings on the uptilted side are held closer to the abdomen at angles of 160° or 200°, very near their closed position. As flight continues, the up-tilted side wings tend to be folded away while the down-tilted side wings continue to beat. Compensatory displacements of leg and abdomen are also produced. The effects of tilting are similar to those produced by single cercus ablation (Fig. 2*b*, *c* and *d*).

Removal of one cercus causes similar asymmetrical flight in a previously symmetrical flier. Thus when the right cercus is removed (Fig. 2*b*, *c* and *d*) the wings on the right side continue to be held and oscillated during flight as for normal symmetrical flight in the intact animal. The hind wing on the left side, however, is held and oscillated near its closed position at an angle of 200°, and in time, ceases to be used. The forewing, may be held extended and oscillated at first, but it is soon withdrawn, leaving the hind wing oscillating. The main torque is exerted by the right wings and will tend to turn the cockroach clockwise (seen from the front). Compensatory movements of abdomen and legs consisting of a tilting of the abdomen to the left and extension of left legs and flexion of right legs are usually apparent. These compensatory movements will tend to turn the animal in the same direction as torque from the wings.

Removal of both cerci abolishes normal tethered flight (Fig. 2*e*). Forewings remain folded, but hind wings are held at angles of 160° and 200° and oscillated.

These reflexes were highly stable and easily evoked. When a cockroach which was asymmetrically suspended so that it tended to beat its left wings only, had its right cercus removed, it then beat its right wings in the normal flight manner and ceased to use its wings on the left. It was not necessary to remove the cerci to evoke these reflexes. Interference with the sensory hairs by smearing with mineral jelly caused asymmetrical flight as if the inactivated cercus had been removed. After removal of the jelly, flight was symmetrical as before.

It seems clear that the cerci should be regarded as equilibrium organs which control equilibrium and compensatory reflexes important in flight. This suggested equilibrium function is not incompatible with existing suggested functions for cerci as auditory organs, vibration receptors or air movement detectors[4]. Bischof on electrophysiological evidence has assigned a gravity

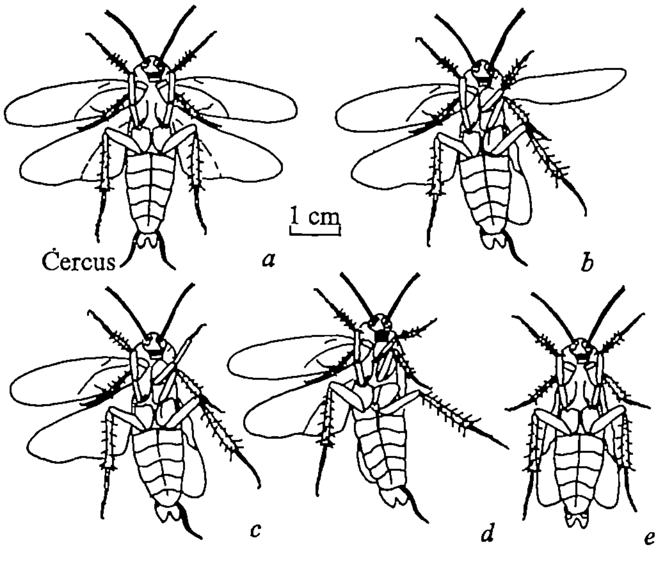

Fig. 2 Frontal views of typical wing and leg positions during tethered flight. *a*, Intact, symmetrically suspended cockroach; *b–d*, right cercus removed showing successive lack of use of left wings; *e*, both cerci removed. Hind wings only are oscillated and are not fully extended.

reception function to club-shaped hairs on the cerci of a cricket[6]. The simplest explanation for the effects reported here is the gravity receptors on cockroach cerci control equilibrium reflexes involving wings and legs in an analogous way to the control of eyestalk and appendage movements by the crustacean statolith[7]. But during inherently unstable locomotion such as flying, an angular movement detector might be expected, analogous to the semicircular canal system of crabs[7,8], facilitating rapid activation of compensatory reflexes. The directional wind sensitive hairs of the cerci could function in this way to detect changes in the velocity of air relative to the cerci which would be caused by angular displacement of the cockroach during forward flight (although many other widely distributed mechanoreceptors, could provide such information[9]).

Transfer of mitochondria by protoplast fusion in *Saccharomyces cerevisiae*

INTRASPECIFIC and interspecific transfer of nuclear genes of fungi has recently been achieved by fusion of protoplasts[1–6]. We describe here the transfer of mitochondrial genome using the protoplast fusion technique. The experiments were carried out with strains of identical mating-type, so we also report successful complementation of auxotrophic yeast cells of the same mating-type after protoplast fusion.

The main steps of the experiments were as follows: (1) selection of a mitochondrial donor with stable nuclear and mitochondrial markers, and of a recipient with a nuclear colour marker and ρ^0 petite mitochondrial character. In both cases it was an additional requirement to have strains of identical mating-type to exclude the possibility of mitochondrial transfer by zygote formation; further, rapid and complete protoplast formation, followed by high-frequency reversion to intact cells, was also a basic necessity. (2) Protoplast formation. (3) Induction of fusion of donor and recipient protoplasts and selective regeneration of those undergoing complementation. (4) Characterisation of the fusion products. And (5), recovery of the recipient containing the marked mitochondria of the donor.

The uracil and tryptophan-requiring strain IL 216-1B (nuclear genotype: α *ura*1, *trp*1; mitochondrial genotype: ω^+ E^R_{221}) was selected as mitochondrial donor. The oxygen-consumption of log-phase cells in yeast extract–glucose medium was 21.8 μl O_2 per mg wet weight per h. This strain can grow on non-fermentable carbon sources in the presence of a high concentration (5 mg ml^{-1}) of erythromycin. A ρ^0 petite mutant of the erythromycin-sensitive (0.2 mg ml^{-1}) adenine-requiring grande strain DV 147 (nuclear genotype: α, *ade*2) was selected as mitochondrial recipient. In the petite mutant no mitochondrial DNA was detected by sensitive fluorescent staining techniques using 4′,6-diamidino-2-phenylindole (DAPI) (refs 6, 7) or 2-[2-(4-hydroxyphenyl)-6-benzimidazolyl]-6-(1-methyl-4-piperazyl) benzimidazole.3HCl (33258 Hoechst)[7] in CsCl gradients. The recipient showed no respiration and was unable to grow on non-fermentable carbon sources or galactose. On minimal medium supplemented with adenine (optimum 5 μg ml^{-1}), the grande DV 147 strain formed fast-growing red colonies, while the colonies of the petite mutant were slow-growing and white.

For protoplast formation the cells were cultivated in yeast extract–glucose medium, collected in the early log-phase, treated with 1% 2-mercaptoethanol[8] for 10 min, collected by centrifugation, resuspended in 0.7 M KCl containing 0.1% 2-mercaptoethanol and 1% snail enzyme to give a final cell concentration of 10^8 ml^{-1}, and gently shaken at 30 °C. All the cells were converted into protoplasts in 1 h; these were collected and washed twice with 0.4 M $CaCl_2$ by centrifugation, and the two strains were then mixed in a 1:1 ratio (5×10^7 protoplasts each). The fusion process was carried out with 35% polyethylene glycol (PEG, molecular weight 4,000) as described previously[2,9]. The suspension of aggregated protoplasts was diluted with 35% PEG, mixed at 43 °C with vitamin-containing[10] minimal medium supplemented with 0.4 M $CaCl_2$ and 2% agar, and poured as a thin top layer on to a similar medium. In this medium, only fusion products complemented nutritionally by heterokaryon or diploid (polyploid) formation between the two partners taking part in the fusion process can regenerate and grow into colonies of wild phenotype.

No colonies appeared if intact cells or protoplasts of only one of the partners were applied; if intact cells of the two partners were cultivated together for mating; or when no PEG treatment was used for aggregation of protoplasts. This means that no back-mutation was observed; no complementation occurred with intact cells of identical mating type; and PEG treatment is essential to induce the fusion process of yeast protoplasts. On the other hand, good regeneration and colony growth was observed in all these cases in nutritionally-sufficient agar media.

The complementation frequency proved to be about 0.04% if all protoplasts taking part in the fusion process were considered, and about 0.6% if the number of colonies growing in minimal medium was compared with the number developing in nutritionally-rich medium. In the present fusion system, the frequencies obtained were similar to those not only for other α+α or *a*+*a*, but also for α+*a* pairs of protoplasts (unpublished), indicating that the protoplast fusion is not affected by mating factors.

The main characteristics of the nutritionally-complemented and regenerated fusion products were as follows. On or in minimal and rich media their cultures, always white, grow more intensively than the fusion partners in optimum conditions, with increased formazan production if tetrazolium violet (20 μg ml^{-1}) was applied in the media. These properties are indications of enhanced metabolic processes. In the fusion products only one nucleus per cell was demonstrated by staining with acridine orange[11]. The average cell size of the fusion products was significantly larger than that of either of the partners. The sizes and DNA determination data are given in Table 1. DNA was extracted by the Bostock procedure[12] and estimated with diphenylamine[13,14] using chicken erythrocyte DNA as standard. A bracketed symbol [x+y] is proposed for the fusion products, at least until they have been characterised thoroughly.

Table 1 Cell sizes and DNA contents of the fusion partners, fusion products, and erythromycin-resistant haploid and aneuploid segregants.

Strains	Length (μm)	Width (μm)	DNA content (fg DNA per cell)
IL 216-1B ρ^+ E^R	5.37±0.14	4.82±0.12	24.4±1.8
DV 147 ρ^0	4.73±0.16	4.43±0.13	22.5±2.3
[IL 216-1B ρ^+ E^R+DV 147 ρ^0]	7.57±0.15	5.42±0.15	48.0±4.1
DV 147 ρ^+ E^R (haploid)	5.62±0.17	5.30±0.16	22.5±0.3
DV 147 ρ^+ E^R (aneuploid)	5.55±0.14	5.04±0.13	30.7±0.6

Values are ± s.e.m. Standard errors are based on 50 measurements and at least three DNA determinations.

These data, together with the observation that the fusion products can be induced to undergo haploidisation, suggest that the fusion products were diploids. No spore formation and only rare spontaneous haploidisation, with a frequency of less than 10^{-4}, has yet been demonstrated. All fusion isolates were resistant to erythromycin at the same level as the donor strain.

By induced haploidisation with *p*-fluorophenylalanine[15-16] (400 to 600 μg ml^{-1}) or with benomyl[17-18] (6–15 μg ml^{-1}) in yeast extract–glucose medium, up to 40% adenine-requiring haploid and aneuploid red colonies with α genome could be isolated. These colonies consisted of respiration-sufficient cells harbouring mitochondrial resistance to erythromycin, indicating successful mitochondrial transfer. Among the resulting adenine-requiring E^R isolates, several proved different from the original DV 147 strain in certain properties. One was the generation of a much lower amount (< 2%) of spontaneous petites, in contrast to the case with the original strain (up to 60%). These properties are under investigation.

Mitochondrial transfer by protoplast fusion—'transfusion' of mitochondria—may contribute considerably to mitochondrial biochemistry and genetics. Not only intraspecific, but also interspecific mitochondrial transfer and recombination of mitochondrial DNA of distant species seems feasible and this possibility is currently under study. It additionally seems of interest to exploit the possibility of fusion of protoplasts of identical mating-type and in this way to build up various α, *a* or specially mixed nuclear genomes for basic research and practical applications, by overcoming the mating-type barrier.

We thank Drs D. H. Williamson and B. Dujon for the strains, Drs D. H. Williamson and O. Dann for DAPI, Dr H. Loewe for 33258 Hoechst, and Mrs Mária Kiss, Mr L. Nagy, Mrs Eva Forrai and Miss Magdolna Romváry for technical assistance.

Circular linkage map of *Rhizobium meliloti* chromosome

GENETIC studies on symbiotic nitrogen-fixing rhizobia are greatly hampered by the lack of an efficient system for genetic mapping in rhizobia. Although there have been reports on transformation[1-3] and transduction[4] in nodulating rhizobia as well as conjugation[5] in a non-nodulating strain of *Rhizobium lupini*, the genetic map of a nodulating and nitrogen-fixing *Rhizobium* strain has not been established yet. Plasmids of the P-1 incompatibility group have a remarkably wide host range and can be transferred to many *Rhizobium* species[6,7]. Some of these plasmids can promote chromosome transfer in *Pseudomonas aeruginosa* strain PAT but show little chromosome donor ability (Cda) in strain PAO[8,9]. Recently a variant (R68.45) of the P group plasmid R68, with high Cda property in strain PAO, was isolated by Haas and Holloway[10]. Plasmid R68.45, unlike most of the sex factors, promotes chromosome transfer for a range of chromosomal genes in *Rhodopseudomonas*, *P. putida*, *Escherichia coli* (B. W. Holloway, personal communication) and in *Rhizobium leguminosarum*[11]. We have found that this plasmid can promote chromosome transfer also in *Rhizobium meliloti* and can be used for mapping of the chromosome. We present here a circular genetic map of the *R. meliloti* 41 chromosome and describe a new approach in the evaluation of conjugational mapping data which may be applicable to other Gram-negative bacteria.

Plasmid R68.45 was introduced into *R. meliloti* 41 strains AK208 and AK209, and the chromosome donor ability (Cda) of the product was investigated. Various auxotrophic and antibiotic resistance markers were used as chromosomal markers in plate matings on nutrient agar[12]. As seen in Table 1, R68.45 could be transferred between *R. meliloti* strains at frequencies of (3–7)×10^{-1} per donor cell and recombinants for various markers were produced at frequencies of 10^{-3} to 10^{-5} per donor cell. This frequency of recombination is about the same as that found in *P. aeruginosa* PAO[10] and about 2–3 orders of magnitude higher than in *R. leguminosarum*[11]. Recombination

Table 1 Plasmid transfer and chromosome mobilisation by R68.45 in *R. meliloti*

Donor	Recipient	Frequency of Tc^R transconjugants	Selected chromosomal marker	Recombination frequency
AK208	AK80	6.3×10^{-1}	*cys*46$^+$	3.6×10^{-4}
			*str*1	1.9×10^{-4}
AK208	AK193	5.2×10^{-1}	*gly*1$^+$	2.8×10^{-4}
			*met*2$^+$	2.6×10^{-4}
AK209	AK80	3.2×10^{-1}	*cys*46$^+$	1.2×10^{-4}
			*str*1	8.0×10^{-5}
AK209	AK193	4.4×10^{-1}	*gly*1$^+$	1.3×10^{-4}
			*met*2$^+$	1.5×10^{-4}

Mating conditions in all experiments were as described before[12]. Selective medium: minimal medium (GTPS[12]) was supplemented with amino acids, 50 μg ml^{-1}; bases, 25 μg ml^{-1}; streptomycin, 100 μg ml^{-1}; rifampicin, 100 μg ml^{-1}; tetracycline-HCl, 15 μg ml^{-1}, as required. Agar surface matings were carried out for 16 h at 37 °C. Bacteria were scraped off the surface of the plates, resuspended in saline and plated on selective media. Counterselection for AK208 and AK209 was by *his*1 and *ura*29, respectively. Strains are described in Table 2. Transfer frequency: Tc^R transconjugants per donor bacterium. Recombinants on same basis.

Table 2 Linkage analysis of various marker pairs of *R. meliloti*

Donor	Recipient	Marker pairs		Linkage c	Distance d	Additive distance
AK213	AK80	*cys*46$^+$	*rif*1	0.10	0.54	
		*str*1	*rif*1	0.73	0.10	
		*cys*46$^+$	*str*1	0.04	0.66	0.64
AK213	AK193	*cys*46$^+$	*rif*1	0.16	0.46	
		*met*2$^+$	*rif*1	0.05	0.63	
		*gly*1$^+$	*rif*1	<0.01	—	
AK208	AK193	*cys*46$^+$	*met*2$^+$	<0.01	—	
		*gly*1$^+$	*ade*4$^+$	0.75	0.09	
		*ade*4$^+$	*met*2$^+$	0.33	0.31	
		*gly*1$^+$	*met*2$^+$	0.22	0.40	0.40
AK208	AK194	*tyr*1$^+$	*gly*1$^+$	0.79	0.08	
		*gly*1$^+$	*ade*4$^+$	0.77	0.08	
		*tyr*1$^+$	*ade*4$^+$	0.66	0.13	0.16
AK208	AK184	*gly*1$^+$	*leu*4$^+$	0.06	0.61	

Strains: AK80: *cys*46 (F46 of ref. 14); by successive mutagenesis with nitrosoguanidine (NTG)—AK193: *cys*46, *gly*1, *ade*4, *met*2, *str*1; AK194: *cys*46, *gly*1, *tyr*1, *str*1; AK184: *cys*46, *gly*1, *leu*4, *str*1. AK213: *his*1, *str*1, *rif*1 (R68.45) by transconjugation of a spontaneous *rif*1 mutant of AK74, *his*1, *str*1 (A1 of ref. 13)—AK208: *his*1, *str*1 (R68.45) by transconjugation of AK74. Counterselection for donors by *his*1; selected for single markers, other marker by replica plating, averaged value for both directions. Strains used in other Tables: AK171 and AK173: *met*33 and *ura*29 mutants by NTG from ZS1, an *ade*1, *str*1 mutant of Z. Sváb; AK209: *ade*1, *ura*29, *str*1 (R68.45) by transconjugation of AK173; GY23: *cys*46, *gly*1, *leu*4, *str*1 (R68.45) by transconjugation of AK184; AK189: *cys*46, *gly*1, *ade*4, *str*1 (R68.45) by transconjugation of plasmid into a two-step NTG mutant of AK80.

frequencies for various markers were essentially the same when different donors were used, so this suggests that R68.45 promotes gene transfer from several chromosomal sites in *R. meliloti*.

We found that R68.45 can lose its Cda property during growth but other properties of the plasmid, such as resistance and transfer markers, are stably inherited. Therefore special care has to be taken to maintain effective donor cultures, as suggested by Haas and Holloway[10]. Recombinants selected for various chromosomal markers were stable but in many instances (10–80%) plasmid markers (TcR or Cda) were partially or completely lost in the recombinants, irrespective of the chromosomal marker selected. These observations also indicate that plasmid R68.45 behaves in *R. meliloti* 41 as it does in *P. aeruginosa* PAO. In recombinants selected for given chromosomal marker and possessing intact R68.45, R68.45 promoted the transfer of the given marker and of various other markers at the same frequency. This suggests that R68.45 is not integrated into the chromosome of the recombinants. Furthermore, using mutants of *E. coli* we demonstrated that the appearance of recombinants after chromosome mobilisation by R68.45 requires *rec*A function, as was expected.

Double or multiply-marked derivatives of *R. meliloti* 41 were mated with derivatives of *R. meliloti* carrying R68.45. Recombinants for single markers were selected and coinheritance of unselected markers was determined by replica plating. The linkage data for certain marker pairs are shown in Tables 2 and 3. In repeated experiments the linkage frequency (number of colonies with the phenotype of both selected and unselected markers per colony showing the phenotype of the selected marker) for a given marker pair varied by up to 10%.

Taking linkage (or cotransfer) frequency to be inversely related to the distance between genes, one usually obtains enough information to establish the marker order, but values of cotransfer frequencies are not additive. To establish a genetic map with additive map distances we attempted to transform our linkage data into additive map distances. We found that the map function derived by Wu[15] for transduction was satisfactory for relating our linkage frequency values (c) to the map distance (d) (in arbitrary units) between two markers

$$c = (1-d)^3$$

We calculated and compared the d values and their additivity, for given marker pairs, obtained in separate experiments and in three-factor crosses. Examples for additive distance values, calculated in three-factor crosses, are shown in Tables 2 and 3. Experimentally determined d values are summarised in Fig. 1. Within the limits of our present experimental data, the correlation is fairly satisfactory for c values higher than 0.1.

There is not enough information about the mechanism of chromosome transfer by R68.45 to justify the use of Wu's equation, derived from the assumption that in transduction the donor fragments have nearly constant length and various regions of this fragment are incorporated into the chromosome of the recipient by pairs of crossover events. Nevertheless,

Table 3 Linkage analysis of the *cys*46 region in *R. meliloti*

Donor	Recipient	Counterselected/ selected markers	Unselected classes of recombinants (%)*			Linkage frequency of pairs, c			Map distance d	Additive distance

Strains and markers: see Table 2.

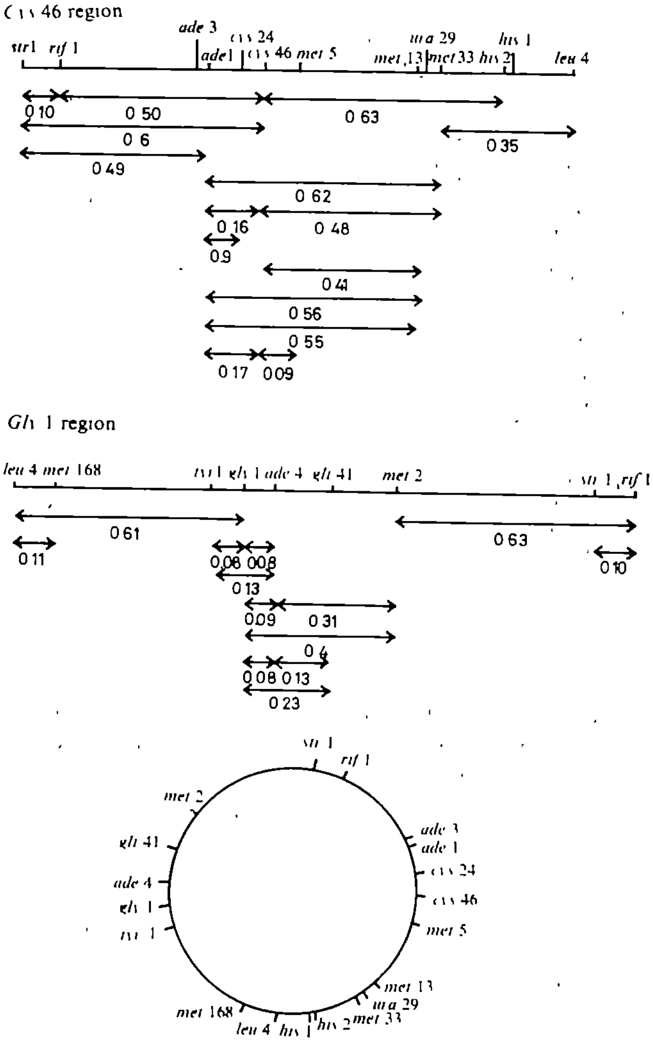
*Unselected marker classes not given were less than 1%.

our data do indicate that the equation is applicable for converting linkage frequencies into approximatively additive map distance values.

The order of markers was determined by calculating map distances between closely linked markers or by three-factor crosses. Data in Table 2 indicate the order *tyr*1–*gyl*1–*ade*4–*met*2–*str*1–*rif*1–*cys*46. Examining the linkage of unselected markers in three-factor crosses gave the linkage data shown in Table 3. From all of these results the order *str*1–*ade*1–*cys*46–*met*33–*ura*29–*leu*4–*gly*1 could be deduced. The results also placed the additional markers *cys*24, *met*5, *met*13, *his*1, *his*2, *met*168 and *glt*41 in relation to the others. By confirming the linking of both ends of the above sequences, a circular map could be established (Fig. 1). The total length of the chromosome is about 3.1–3.2 arbitrary units (*d*). Mutant strains with single markers are being mapped in our laboratory. Using our multiply-marked mutants five matings are enough to locate any mutation on the linkage map.

In the original map function derived by Wu, $c = (1-d/l)^3$ the average size of the transducing particle (l) was known from independent measurements. Applying this equation for our system and using the information that the length of the chromosome is 3.2 d units, the average size of the donor fragment could be calculated. This is about 1/3 of the chromosome. On the other hand, however, in several cases we could demonstrate 0.05–1.0% co-inheritance of markers up to 1.5 d units apart (data not shown). This suggests that about 1% of the donor fragments are at least halves of the total chromosome in size.

Fig. 1 Linkage map of *R. meliloti* 41. Distances between markers are *d* values, obtained directly from independent crosses. Locations of *cys*46, *met*5, *met*13, *his*1, *his*2, *met*168 and *glt*41 were determined in three-factor crosses.



Therefore we could not calculate *d* values from linkage frequency values (*c*), lower than 0.03.

In conclusion, our data indicate that R68.45 is suitable for genetic mapping in *Rhizobium meliloti*. The mapping was based on linkage analysis of chromosomal markers and a circular map of the *R. meliloti* 41 chromosome was constructed. Recently Meade and Signer demonstrated linkage of chromosomal markers of *R. meliloti* 2011, using RP4 as a sex factor[16]. Using R68.45 we are directing our efforts to map those genes which are involved in symbiotic nitrogen fixation.

Although we do not have independent evidence to support our empirical use of the described map function relating linkage frequency to the map distance, we suggest that the map distances between markers are approximately proportional to the physical marker distances around the chromosome. Preliminary experiments in our laboratory indicate that this equation is applicable for linkage frequencies, obtained with R68.45, in *E. coli* as well. Furthermore, this plasmid would be useful for genetic mapping in many other Gram-negative bacteria, and our new approach for evaluating conjugational mapping data will certainly be useful for these future genetic systems.

We thank Dr L. Orosz for helpful discussions, Professors R. D. Hotchkiss and P. Schaeffer and Dr M. Gábor-Hotchkiss for assistance and Professor B. W. Holloway for providing plasmid R68.45.

Note added in proof: Drs J. E. Beringer and A. W. Johnston have informed us that they have established a circular linkage map of *R. leguminosarum* chromosome[17] and have demonstrated interspecific recombination mediated by R68.45 among various *Rhizobium* species[18]. A linkage map of *R. meliloti* has recently been reported by Meade and Signer[19].

Very close linkage between HLA-B and Bf inferred from allelic association

The human leukocyte antigen loci (HLA, previously HL-A) are known to be closely linked to the locus defining factor B of the alternative complement pathway[1]. The B-factor locus was previously termed GBG (glycine-rich β-glycoprotein) and is now known as Bf. If the consequences of recombination do not impair survival we may use data on allelic association (sometimes termed linkage disequilibrium) as a rough estimate of the upper limit of the recombination fraction, θ. This approach has advantages

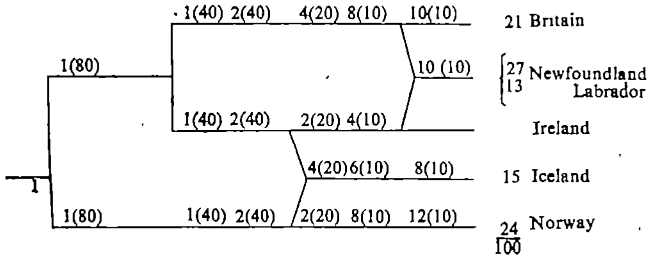

Fig. 1 A 'family tree' of the populations studied. Dimensions are time in generations (in brackets) and assumed numbers of ancestral B8 loci (minimum plausible estimates).

where linkage is very close and the frequency of laboratory and other errors in ascertaining recombinants is greater than the recombination frequency. By typing two or more members of families we have defined 100 apparently independent haplotypes with the HLA-B allele B8 and all had the Bf allele S. These observations were fairly evenly divided between Iceland, north-west Newfoundland and Labrador, Central England and Norway. Figure 1 shows a 'family tree' of these populations.

Iceland was settled in AD 874 by Norsemen with Irish slaves and had a population of over 70,000 by AD 1100; the Nordic and Celtic genetic contributions seem to have been comparable[2]. Newfoundland was settled more slowly, but was substantially settled over 200 yr ago, mainly from England and Ireland. There are few data on the time of separation of the main Celtic, Saxon and Norse groups, or on the scale of the Saxon invasions.

The dimensions of the tree are time in generations (in brackets) and inferred minimal numbers of ancestral haplotypes. The number of individuals bearing the haplotype who were the ancestors of the tested population cannot be known, but can never have been greater than in the tested population. At some point in history all the tested populations had common ancestors and, in the remote past, there must have been a common ancestor of all the tested individuals. We feel that the dimensions of the tree are not unreasonable and are intentionally highly conservative, as is the assumption of a single ancestral haplotype at 3000 BC.

There are no apparent recombinants between the B and Bf loci in our sample. The chance of none of c haplotypes recombining in n generations is $(1-\theta)^{cn}$. The chance of an S allele being replaced by another is the relative proportion of these others, which is about a third in our population, so that the chance of no evident recombinant is $(1-\theta/3)^{cn}$ According to our assumptions, cn over all links is about 2,000. The table shows the probability of B8 alleles being exclusively associated with S on assumptions of various recombination fractions, assuming no selection against recombinants. While mild selection against recombinants will explain a substantial deficiency of B8-F haplotypes, a very strong selective disadvantage would have to be postulated to explain the complete absence of contemporary recombinants in such extensive data.

Table 1 Probabilities of no detectable recombinant in 1,500 and 3,000 meioses

θ	1,500	3,000
0.001	0.60	0.37
0.002	0.37	0.14
0.003	0.22	0.05
0.004	0.14	0.02
0.005	0.08	0.01
0.006	0.05	
0.008	0.02	
0.010	0.01	

We are aware of slight selective bias in selecting the B8 allele for special consideration; however, this allele is of particular interest for other reasons. One B8-F_1 haplotype has been reported by Hauptmann *et al.*[3]. This variant is usually associated with B18 in our experience. Albert *et al.*[4] also found a complete and significant deficiency of B8-F (0/30) haplotypes in Germany, where Bender *et al.*[5] found 4 B8-F haplotypes, 1 B8-S_1 and 64 B8-S, and also reported a B18-F_1 haplotype. B18 is also allelically associated with deficiency of the second component of complement (C2).

We consider our data to be evidence of very close linkage between the loci of B and Bf. If the determinants relating to graft survival are stronger at the B locus or are determined by loci which are closer to this locus than to the A locus, Bf-typing might be of more practical value than HLA-A typing. It may also provide *a priori* evidence suggestive of a serologically definable split when one B allele is commonly associated with more than one Bf allele.

Factors from 3T3 cells stimulate proliferation of cultured vascular endothelial cells

TUMOURS induce vascularisation into the neoplasm to provide needed cell nutrients and remove wastes[1]. The formation of tumour blood vessels seems to depend, in part, on the proliferation and movement of vascular endothelial cells which are, in turn, controlled by the secretion of tumour angiogenesis factor (TAF) (refs 2–4). Extracts of tumours[2-4] and of established cell lines[5] have TAF activity *in vivo* But little is known about the molecular nature or mechanism of action of TAF. The proliferation, formation and integrity of vascular endothelium are also involved in normal host processes· wound healing, morphogenetic tissue rearrangements, as well as the prevention of various non-neoplastic diseases resulting from blood vessel wall injury depend on angiogenesis factors[6]. A convenient method to study angiogenesis and endothelial repair is with an *in vitro* endothelial cell system, but the lack of uniform, reliable cultured endothelial cell lines has delayed progress in this area. Most studies[7-9] (with some exceptions[10]) have used uncloned vascular cells which are often slow growing and heterogeneous in cell type. We have recently established a cloned adult bovine aortic endothelial (ABAE) cell line which has maintained its endothelial properties for over 1 yr in culture, provided that fibroblast growth factor (FGF) is present in the growth medium[11]. We report here the mitogenic effects of several untransformed and transformed cell lines on cloned ABAE cells and non-vascular endothelial cell controls.

Endothelial cell mitogenesis was monitored by seeding ABAE or control non-vascular adult bovine corneal endothelial (ABCE) cells on to γ-irradiated feeder layers of test cell cultures and measuring the proliferation of the unirradiated endothelial cells in the absence of FGF. All cells were cultured in Dulbecco modified Eagle's medium (DMEM) (ref. 12) with 10% calf serum. When vascular ABAE cells were seeded on to γ-irradiated feeder layers of MSV-transformed BALB/c 3T3 (MSV3T3) or BALB/c 3T3 (clone A·31) cells, substantial proliferation of ABAE cells occurred within two days (Fig. 1*a*). By 12 days ABAE cells grew to almost 100 times the density of ABAE cells grown in DMEM with 10% calf serum (Figs 1*a* and 2). MSV3T3 cells were almost as effective as FGF (100 ng ml^{-1}) and more effective than BALB/c 3T3 cells in promoting growth of ABAE cells, while NIH Swiss 3T3 and ABAE feeder cells had little effect on ABAE cell mitogenesis (Fig. 1*a*). When non-vascular ABCE cells were substituted for ABAE cells, none of the cell lines tested stimulated ABCE cell proliferation, although ABCE cells do respond to FGF (Figs 1*b* and 2). Several other γ-irradiated untransformed cell lines were tested for their ability to promote the growth of ABAE cells. Although some of these cell lines caused slight increases in ABAE cell growth (15–41% over controls), none of the lines was judged to be significantly mitogenic to ABAE cells (Table 1). Thus far, every transformed cell line tested has stimulated ABAE but not ABCE cell proliferation (C.R.B. and G.L.N., to be published).

The proliferative effects of γ-irradiated BALB/c 3T3 and MSV3T3 cells on ABAE cells were due to substances released by the feeder cells and were not due to artefacts of γ-irradiation. This was demonstrated by experiments where the effects of conditioned medium from unirradiated feeder cells on ABAE cell proliferation were measured. Conditioned medium from BALB/c 3T3 and MSV3T3 cells stimulated growth of ABAE cells approximately 20 and 30 times, respectively, over ABAE cell growth in DMEM with 10% calf serum (Fig. 3). Although this was less than the effect of γ-irradiated BALB/c 3T3 or MSV3T3 cells on ABAE cell proliferation, it indicates that the former cell lines release an ABAE growth promoting factor(s) into the medium. Conditioned medium from ABAE cells was slightly more effective than γ-irradiated ABAE cells in promoting proliferation of the same cells but was much less effective than conditioned medium from BALB/c 3T3 or MSV3T3 cells. Conditioned medium from unirradiated BALB/c 3T3 or MSV3T3 did not stimulate proliferation of non-vascular ABCE cells (data not shown). These effects were not due to γ irradiation, because conditioned medium from γ-irradiated cells had the same effect as conditioned medium from non-irradiated cells, and mitomycin c-treated cells produced similar prolifera-

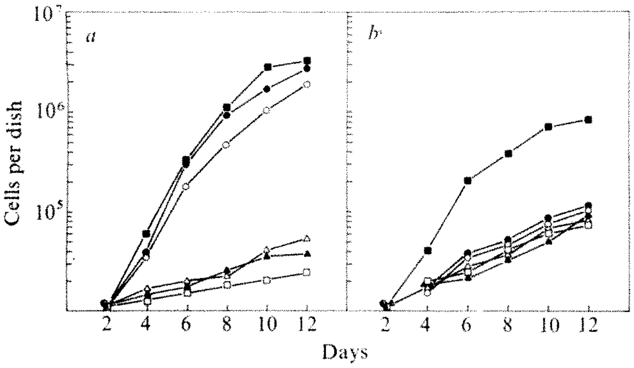

Fig. 1 Growth of adult bovine endothelial cells on γ-irradiated cells. *a*, Aortic endothelial cells; *b*, corneal endothelial cells. The cloning, culturing and characterisation of adult bovine aortic[11] and corneal[13] endothelial cells have been previously described. The aortic endothelial cells are routinely cultured in the presence of 100 ng ml^{-1} of FGF, which was purified as described[14,20]. BALB/c 3T3 cells (clone A·31) and MSV3T3 cells (murine sarcoma virus-transformed clone A·31 BALB/c 3T3 cells) were obtained from Dr S. Aaronson of the National Cancer Institute, Bethesda, MD. BALB/c 3T3 cells grew as a density-inhibited line and were non-tumorigenic when 10^6 cells were injected subcutaneously into BALB/c mice, whereas MSV3T3 cells had lost density-inhibition of growth and formed large tumours when 10^6 cells were injected subcutaneously into BALB/c mice. NIH Swiss 3T3 cells were obtained from Dr K. Jones of the University of California, San Diego. All cell lines were cultured at 37 °C on Falcon tissue culture dishes in Dulbecco modified Eagle's medium (DMEM)[12] supplemented with 10% calf serum (Gibco). The *in vitro* assay of endothelial cell proliferation using γ-irradiated cells was conducted as follows. Six dishes were seeded 10,000 test cells in DMEM with 10% calf serum, and after the cells had attached (4–12 h), the dishes were γ-irradiated with a total of 6,000 R from a ^{60}Co irradiator to block cell division. The medium was then removed and 5,000 endothelial cells were seeded in DMEM with 10% calf serum on top of the test cell feeder layer. The following controls were employed: dishes of irradiated test cells alone, endothelial cells grown on γ-irradiated endothelial cells, and endothelial cells alone grown in the presence and absence of FGF (100 ng ml^{-1}); FGF was added every other day. In some experiments, confluent dishes of test cells were irradiated as described, removed from the dishes by trypsinisation and then seeded at 10,000 cells per dish. This did not alter the results of any experiments. Every other day after the addition of endothelial cells the medium was replaced on all dishes, and duplicate cultures were trypsinised and counted with an electronic cell counter (Electrozone/Celloscope, Elmhurst, Illinois). The number of endothelial cells growing on test cell feeder layers was corrected for the number of cells on dishes of test cells alone. The experiments were conducted five times and representative results are shown. □, Endothelial cells alone (*a*, aortic; *b*, corneal); ■, FGF (100 ng ml^{-1}); ●, γ-irradiated MSV3T3 feeder layer; ○, γ-irradiated BALB/c 3T3 feeder layer; △, γ-irradiated NIH Swiss 3T3 feeder layer; ▲, γ-irradiated endothelial feeder layer (*a*, aortic; *b*, corneal).

Fig. 2 Stained dishes of adult bovine endothelial cells growing on γ-irradiated cells. The experiment was conducted as described in Fig. 1. After 12 days the medium was removed and cells were stained with Diff-Quick (Harleco, Gibbstown, NJ). Control dishes were endothelial cells grown alone in DMEM with 10% calf serum. tive effects on ABAE cells when compared with γ-irradiated cells (C.R.B. and G.L.N, to be published).

The cloned ABAE cells used in the experiments here have been well characterised as endothelial cells[11]. They can be continuously passaged in tissue culture without loss of endothelial cell characteristics when grown with purified FGF, however, in the absence of FGF they form small colonies of vacuolated, irregularly-shaped cells[11,20]. Our results indicate that vascular ABAE, but not non-vascular ABCE cells, are sensitive to growth factors released into the medium by certain cultured cells. The relationship between these 'factors' and FGF is unknown, although these substances do not stimulate proliferation of ABCE cells which respond to FGF. Recent studies have demonstrated the effects of conditioned medium from various tumour cell lines on primary cell cultures from human umbilical cord endothelium[4] and also the mitogenic properties of tumour cell homogenates on cultured foetal bovine aortic endothelial cells[9]. In both cases, the endothelial cells were mixed populations of uncloned cells and could not be passaged continuously. The cloned ABAE cells[11] should prove useful for endothelial cell proliferation studies, although it is important to note that the control of cell growth *in vitro* may differ from control *in vivo*.

Our findings that untransformed BALB/c 3T3 (A·31), but not untransformed NIH Swiss 3T3, cells significantly stimulate ABAE but not ABCE, cell growth may be related to other observations concerning BALB/c 3T3 cells. When BALB/c 3T3 (A·31) cells adherent to glass[21] or plastic[22] are implanted subcutaneously into BALB/c mice, haemangioendotheliomas[21] or vasoformative sarcomas[22] are formed, and Boone has suggested, on the basis of these experiments, that BALB/c 3T3 (A·31) cells may be preneoplastic. These results, together with morphological studies on BALB/c 3T3 cells[23] show that BALB/c 3T3 cells are probably of endothelial rather than fibroblast origin. BALB/c 3T3 cells possess nerve growth factor[24] and TAF (ref. 5) activities, but it is unclear if the presence of these factors is related to a preneoplastic state. If BALB/c 3T3 cells are endothelial in origin, our results cannot be simply interpreted as a conditioning effect of one type of endothelial cell on another, because ABAE cells have little effect on ABAE cell proliferation (Fig. 1*a*).

The nature of the factor(s) released by BALB/c 3T3 and MSV3T3 cells in our experiments is unknown. It seems to be different from FGF, since FGF but not BALB/c 3T3 or MSV3T3 cells stimulated non-vascular ABCE cells to proliferate (Figs 1*b* and 2). As mentioned earlier, Klagsburn *et al.*[5] have shown that extracts of BALB/c 3T3 cells induce vascularisation when placed on the chorioallantoic membrane of the chicken embryo, whereas BALB/c primary mouse embryo fibroblasts have no effect. We have likewise found that BALB/c 3T3 cells, but not BALB/c primary mouse embryo fibroblasts, will stimulate the proliferation of ABAE cells *in vitro*. It is unlikely that secreted proteolytic enzymes are responsible for the effects of BALB/c 3T3 cells on ABAE cells, since proteolytic enzymes such as thrombin have no effect on ABAE cell proliferation (D. Gospodarowicz, K. S. Brown, C. R. Birdwell and B. Zetter, to be published). Further study will be necessary to ascertain if the reported TAF activity of BALB/c 3T3 cells[5] is responsible for the proliferation of ABAE cells *in vitro*. If this is the case, however, our results are the first to demonstrate that TAF is active *in vitro* as well as *in vivo*.

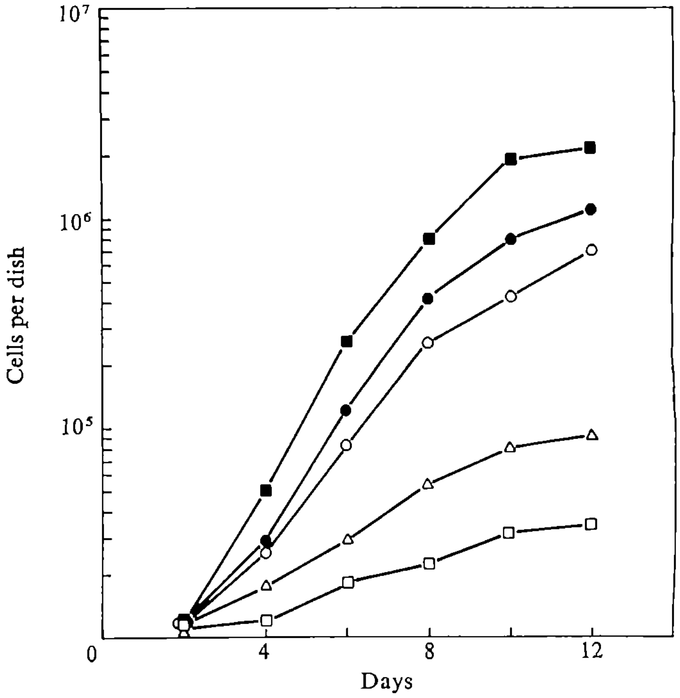

Fig. 3 Growth of adult bovine aortic endothelial cells in conditioned medium. For preparing conditioned medium of BALB/c 3T3 and MSV3T3 cells, 10^5 cells were seeded on to 10-cm dishes in 10 ml of DMEM with 10% calf serum. When the cells were subconfluent (about 4×10^6 cells per dish), the medium was removed, clarified by low-speed centrifugation and filtered through a 0.22-μm filter, then frozen for storage. For preparing conditioned medium of adult bovine aortic endothelial cells, 10^6 cells were seeded as described, since these cells proliferate poorly when seeded at low densities in the absence of FGF. For growth rate studies, adult bovine endothelial cells were seeded at 5,000 cells per 6-cm dish in DMEM with 10% calf serum and after the cells had attached (4–12 h), the medium was replaced with fresh medium or the appropriate conditioned medium. Every other day after the addition of endothelial cells the medium was changed, and duplicate cultures were counted as described in Fig. 1.; FGF was added every other day. The experiments were conducted three times and representative results are shown. ■, FGF (100 ng ml^{-1}); □, DMEM with 10% calf serum; ●, MSV3T3 conditioned medium; ○, BALB/c 3T3 conditioned medium; △ aortic endothelial cell conditioned medium.

Table 1 Effect of various cell lines on the proliferation of adult bovine aortic endothelial cells

Cell line*	% proliferation†
Bovine vascular smooth muscle cells	23
Bovine granulosa cells	18
Bovine corpus luteal cells	31
Bovine corneal epithelial cells	33
Bovine lens epithelial cells	28
Rat 31A ovarian cells	14
C57BL/6J primary embryo fibroblasts	29
BALB/c primary embryo fibroblasts	41

*The cloning and culturing of bovine smooth muscle[11], granulosa[16], corpus luteal[17], corneal epithelial[18], lens epithelial[18], and rat 31A ovary[19] cells have been previously described. Mouse primary embryo fibroblasts were established by trypsinising 16 d-old embryos of C57BL/6J and BALB/c mice, respectively. All cell lines were cultured in DMEM with 10% calf serum (Gibco). The cell lines were tested for proliferative effect as described in Fig. 1, except that cultures were counted only on the twelfth day after the addition of endothelial cells.

†Refers to the percentage increase in the number of endothelial cells on γ-irradiated test cell feeder layers over the number of endothelial cells grown alone in DMEM with 10% calf serum.

These studies were supported by grants from the US Public Health Service, US NSF and American Cancer Society and a contract from the Tumor Immunology Program of the US National Cancer Institute to G.L.N. C.R.B. is a US Public Health Service Fellow. We would like to acknowledge the expert technical assistance of Adele Josepho.

A T cell-replacing factor specific for histocompatibility antigens in mice

COLLABORATION between thymus-derived (T) and non-thymus-derived (B) lymphocytes in immune responses to many antigens has long been established[1]. The actual mechanism of this collaboration, the role of macrophages, and whether it requires contact between the cells or is mediated by soluble factors is still under discussion. Although antigen-specific factors have been reported[2–7], many T-cell replacing factors which have been described are not specific for the antigen used to prime T cells (see ref. 8 for review). Most of these non-specific factors have been obtained from cultures of allogeneic lymphocytes[8–11]. We describe here a specific factor(s) obtained from lymphocytes stimulated *in vitro* by allogeneic cells. This factor replaces helper T-cells in an *in vivo* antibody response to the histocompatibility (H) antigens of the stimulating cells but not to other H antigens or to sheep erythrocytes (SRBC). This is the first description of a factor specific for H antigens which replaces T-cells in T–B collaboration.

Mixed spleen and lymph node cells from BALB/c (H–2^d) mice were stimulated in mixed lymphocyte culture (MLC) by C3H (H–2^k) cells. After 10 d in culture, the alloantigen 'primed' BALB/c lymphocytes were centrifuged and the supernatants were saved (culture supernatant). The cells (90–95 % θ-positive T cells) were washed and resuspended in medium without serum at a concentration of 25×10^6 per ml and incubated at 37 °C for 4 h. The cell-free supernatant was collected after centrifugation (primed cell supernatant) and 0.2 ml was injected intravenously into BALB/c-nu (nude) mice immediately or after storage at −20 °C. After 2 weeks the nude mice were immunised against C3H and C57B1/6 (H–2^b) and tested for their ability to make an antibody response to H–2^k and H–2^b alloantigens. Some nudes were also immunised with SRBC. In this case, mice were immunised first with SRBC since prior immunisation with allogeneic cells has been found to increase the primary antibody response against SRBC (unpublished).

The results of one experiment are presented in Table 1. Nude mice injected with the primed cell supernatant made cytotoxic antibody against C3H cells which were used as stimulators in the MLC. Antibody activity was also detected against CBA cells, which share H–2^k with C3H. In contrast, no antibody activity was detected against C57B1/6 or C3H.SW, a strain congenic with C3H and bearing H–2^b. Nude mice injected with supernatant from unprimed BALB/c cells or those not injected with supernatant did not make an antibody response. One of two nude mice injected with culture supernatant made a low-titred antibody response detected against CBA cells but not with any of the other test cells.

Nude mice given primed cell supernatant made antibody only after immunisation with cells (Table 2). One week after the injection of primed cell supernatant there was no detectable antibody against H–2^k or H–2^b. Following immunisation with cells from both strains, cytotoxic antibody was made to H–2^k only. The titre of the antibody was comparable with that made by normal BALB/c mice. After a second immunisation with C3H and C57B1/6 cells no antibody was made by the nude mice. In contrast, normal BALB/c mice produced higher antibody titres against both H–2 types when boosted.

Table 3 shows the antibody response of nude mice injected with primed cell supernatant or BALB/c lymphocytes and immunised with SRBC. While nude mice reconstituted with BALB/c cells made antibody to SRBC, the primed cell supernatant did not restore the ability of these mice to respond.

These results demonstrate that MLC-primed lymphocytes make a factor(s) which is capable of replacing T cells in the response to H antigens. The antibody response was specific for the H antigens present on the stimulator cell used in the MLC. Thus, factor from BALB/c cells primed against C3H enabled nude mice immunised with cells from C57B1/6 (H–2^b) and C3H (H–2^k) to make antibody which reacted with H–2^k bearing cells but not with H–2^b. The absence of antibody activity to C3H.SW is important since this demonstrates that the antibody responses of nude mice given the primed cell supernatant were restricted to the H–2 region. We do not yet

*The primed cell supernatant was a cell-free supernatant prepared from MLC-primed BALB/c lymphocytes. 40×10^6 BALB/c cells (spleen and lymph node) were stimulated in MLC against 80×10^6 C3H cells (irradiated with 3,300 rad X ray) in 16 ml culture medium in flasks (Falcon 3024). The culture medium was RPMI 1640 made up to 5 % with human serum, buffered with sodium bicarbonate (2 g l^{-1}) and HEPES (25 mM), and supplemented with L-glutamine (2 mM), L-arginine (0.6 mM), L-asparagine (0.3 mM), penicillin (100 IU ml^{-1}) and streptomycin (100 μg ml^{-1})[21]. After 10 d, the primed cells were washed and resuspended at 25×10^6 per ml in RPMI 1640 without serum and cultured at 37 °C for 4 h. The primed cell supernatant was recovered after centrifugation and used immediately or frozen before use. Unprimed BALB/c supernatant was a cell-free supernatant from freshly isolated, BALB/c lymphocytes (pooled spleen and lymph node) prepared in the same way as the primed cell supernatant. Culture supernatant designates the cell-free culture medium from the MLC. 0.2 ml of primed cell supernatant and cell supernatant from unprimed BALB/c lymphocytes were injected intravenously into nude mice; nude mice injected with culture supernatant were given 0.4 ml.

†Maximal antibody activity was measured on day 10 after immunisation intraperitoneally with 10^7 C3H and 10^7 C57B1/6 spleen cells by complement-dependent cytotoxicity using a two-stage method and absorbed guinea pig serum as a source of complement[21]. Responses are given as one/highest dilution at which antibody activity was detected. Each row represents responses of an individual mouse.

‡No cytotoxic antibody detected at a serum dilution of 1/4, the lowest dilution tested.

*Nude mice were injected with 0.2 ml primed cell supernatant 14 days before immunisation by intraperitoneal injection with 10^7 C57 and 10^7 C3H cells. Each row represents the responses of an individual mouse.

†Given as one/highest dilution of serum giving detectable cytotoxic activity. Pre-immune sera from nude mice were tested on day 7 after injection of primed cell supernatant. The largest primary antibody response was measured between days 7 and 10 after immunisation in BALB/c mice and on day 10 in nude mice. Mice were re-immunised 14 d after the initial immunisation and the secondary response was measured 7 d later.

know the determinants within the H–2 complex against which the antibodies react, but K and/or D determinants are presumably involved since these antisera lysed 100% of lymph node cells.

The lack of T cell-dependent responses to SRBC in mice receiving the primed cell supernatant is of interest since a number of studies have demonstrated that alloantigen-stimulated lymphocytes make nonspecific factors which substitute for T cells in an *in vitro* response to SRBC (refs 8–11). But these factors were normally obtained early in the allogeneic reaction and tested *in vitro*. In our experiments the factor was obtained after 10 d in MLC when the proliferative response was ended and most of the responding (blast) lymphocytes had reverted to small cells. This suggests that, while lymphocytes responding in MLC may release nonspecific factors, elaboration of specific factors is either of a longer duration or requires a longer interval between antigenic stimulation and production of specific factor.

Factor with strong activity was recovered in the primed cell supernatants but not in the culture supernatants. The factor may have been present in the culture supernatants but at too low a concentration to be effective. Alternatively, serum components or other substances released by stimulated lymphocytes could have had an antagonistic effect on the activity of the factor.

*Primed cell supernatant (0.2 ml) and culture supernatant (0.4 ml) were injected; 10^7 BALB/c lymphocytes (pooled spleen and lymph node) were injected into control animals.

†Measured as $\log_2$ haemagglutinating activity by 2-mercaptoethanol (2-ME) treated sera, except for the secondary response of the mice injected with supernatant. 2-ME was used because non-reconstituted nudes sometimes make a 2-ME sensitive primary antibody response against SRBC. Antibody responses were measured 7 d after immunisation intraperitoneally with 10^8 SRBC.

The failure to find a secondary response (Table 2) in nude mice injected with the primed cell supernatant argues against a direct effect on precursor T cells known to be present in nude mice[12]. Thus, the factor probably acts directly on specific B cells or has an indirect effect on B cells through macrophages. Conflicting evidence has been presented in the literature concerning the cell type to which antigen-specific factors are directed. Munro and Taussig[13] found that B cells have an acceptor site for antigen-specific factors, suggesting an effect on B cells, whereas Feldmann[14,15] has clearly demonstrated the importance of macrophages in his system.

In our system the nude mice failed to make a detectable antibody response unless challenged with allogeneic cells. Furthermore, the mice were immunised 2 weeks after injection of the primed cell supernatant, demonstrating that the activity of the factor is of long duration. This suggests that antigenic stimulation of specific B cells may not necessarily have to be temporally related to the T-cell help. Such a long term effect of the factor could be due to one of two mechanisms. Either the factor binds directly to specific B cells or to macrophages and is not degraded before antigenic challenge, or the factor gives a signal to the relevant B cells which commits these cells to making antibody on contact with antigen. In the latter case, the signal could result from direct binding to the B cells or after processing by macrophages.

Plate[16] has described a factor which is obtained from MLC activated lymphocytes. This factor substitutes for helper T cells in the generation of cytotoxic T lymphocytes against H antigens. It is not known whether the same T-cell population acts as helpers in antibody production and in the generation of cytotoxic T-cells. But since the specificity of cytotoxic T cells and antibody to major H determinants may be similar[17–20], these systems obviously offer a unique opportunity for dissecting the nature of cell–cell interations in the immune response.

Magnitude of memory to the major histocompatibility complex

ALTHOUGH the phenomenon of memory is central to the adoptive immune response to antigenic stimulation, the magnitude of the memory effect in graft rejection has never been quantified. We have directly compared the potency of naive and memory cells in two quantitative adoptive transfer assays, one measuring graft rejection and the other graft-versus-host activity. While the well known lack of a significant factor of immunisation in the latter was confirmed, memory cells showed a dramatic, long term increase in their potency to reject heart grafts.

Memory of prior exposure to antigens of the major histocompatibility complex (MHC) was shown many years ago to be both long-lived and specific[1]. Long term memory to these antigens involves a surprisingly small quantitative change in immune responsiveness measured by conventional allo-immune assays, however. Naive animals rapidly reject MHC incompatible grafts and rejection of these grafts is not markedly accelerated by prior sensitisation[2]. The factor of immunisation (FI) in graft-versus-host (GVH) assays is also negligible or absent[3,4]. *In vitro*, although there is an acceleration in the kinetics of the response in mixed lymphocyte reactions, memory cells show no quantitative increase in proliferative capacity[5]. In all other immune responses (including those to weak alloantigens), long term memory is associated with a significant quantitative increase in the response[2,3].

It is possible that the failure to demonstrate memory to strong alloantigens reflects a deficiency in the assay systems used rather than the absence of a specific quantitative change in immune responsiveness in the lymphocytes of a host sensitised to these antigens. Evidence suggesting that this is so derives from adoptive transfer experiments. Sensitised cells differ markedly from naive cells in their capacity to terminate tolerance[6] and to reject long-surviving grafts in immunologically privileged sites[7]. In both cases the response measured is primarily an effector response and not a proliferative one.

We have used a quantitative adoptive allograft assay to compare directly the potency of naive and sensitised cells in effecting the rejection of heterotopic heart grafts in irradiated rats. The same two cell populations were also compared in a quantitative GVH assay to detect any change in proliferative capacity resulting from long term sensitisation. Naive rats of the PVG (Ag-B5), DA (Ag-B4) and Lewis (Ag-B1) strains mutually rejected heterotopic adult heart grafts in 6–8 d (Fig. 1*a*). Previously sensitised animals of these strains showed the trivial acceleration of graft rejection which is expected in respect of major alloantigens (Fig. 1*b*). But, when naive and sensitised cells were compared in an adoptive assay rather than in the whole animal a dramatic increase in potency of sensitised cells was demonstrated. Rats irradiated with 750 rad did not reject Ag-B incompatible hearts for at least 40 d (Fig. 1*h*). Adoptive transfer of syngeneic lymphoid cells to irradiated recipients restored their capacity to reject heart grafts and the degree of restoration was related to the number of cells in the restorative inoculum (Fig. 1*d*–*f*). The minimum number of naive thoracic duct lymphocytes (TDL) or lymph node cells (LNC) which would restore graft rejection to first-set time was 500×10^6 (Fig. 1*d*). But, if the restorative inoculum was obtained from PVG donors bearing long term memory to DA alloantigens as few as 5 to 20×10^6 TDL or LNC caused rejection of DA hearts in first-set time (Fig. 1*j*, *k*). This represents an increase in potency of sensitised cells of 25–100-fold. The increase in potency is specific: PVG cells with memory for DA alloantigen behaved as naive cells in respect to Lewis heart grafts (Fig. 1*g*, *l*). Aliquots of the same cells which showed this dramatic increase in potency in respect of heart graft rejection showed no significant factor of immunisation in GVH responses (Fig. 2).

These results show that prior exposure to antigens of the MHC causes a dramatic and specific increase in potency of the cells responsible for allograft rejection but no increase in the proliferative capacity of the cells responsible for the GVH reaction. This suggests that the subpopulation of T lymphocytes which proliferates in a GVH response and that which mediates tissue damage not only respond to different antigenic determinants[8] and carry distinct cell surface markers[9] but might also respond in quite a different manner to prior sensitisation. The successful demonstration *in vivo* of the dramatic and specific increase in allograft reactivity which occurs in the lymphocyte pool of rats which have been sensitised against antigens of the MHC depends on the use of an adoptive assay. A combination of two factors makes it impossible to demonstrate the extent of this change in the intact rat. It is well established that naive animals have large numbers of antigen sensitive cells responsive to strong alloantigens[10,11]. The experiments reported here showed that there is a physiological limit to the speed with which detectable cell-mediated tissue damage can be effected. If less than 500×10^6 normal cells were given to an irradiated host, rejection time was directly

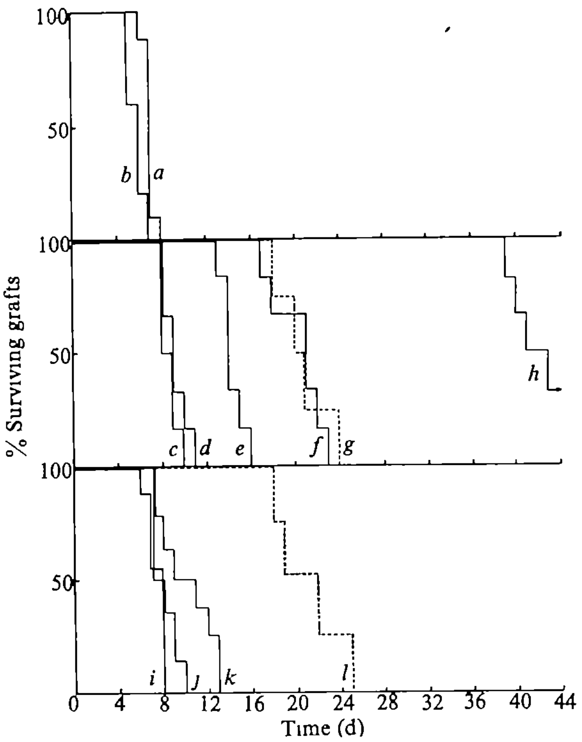

Fig. 1 Life tables of graft survival in PVG rats grafted with DA hearts (solid line) or Lewis hearts (broken line). The aorta and pulmonary arteries of the adult heart grafts were anastomosed to the abdominal aorta and inferior vena cava of the recipient using a modification of the technique of Ono and Lindsey[16]. Rejection was confirmed by loss of electrocardiogram activity. The PVG rats sensitised to DA alloantigens had rejected two sequential DA skin grafts, 6–12 weeks before use. Lines *a* and *b* represent rejection times of DA grafts in normal and sensitised recipients respectively. There is a very small difference in first and second-set rejection times of grafts between Ag-B different strains. *c*–*h* Represent rejection times of grafts in PVG rats given 750 rad on the morning of grafting. Irradiation was from a ^{60}Co source in conditions of maximum back scatter. Within 24 h of grafting groups of these recipients were injected intravenously with graduated doses of LNC from naive PVG rats. Doses of LNC given: *c*, 10^9; *d*, 5×10^8; *e*, 2×10^8; *f*, *g*, 5×10^7. Graft survival was measured from the day of injection with LNC. Irradiated rats given no LNC (*h*) do not reject grafts for 40 d. The minimum number of LNC which will restore first-set rejection was 5×10^8. With smaller numbers of LNC the acceleration of rejection is dose related. *i*–*l* Represent rejection of grafts in irradiated PVG rats injected with LNC from PVG rats sensitised to DA alloantigens. Doses of sensitised LNC given: *i*, *l*, 5×10^7; *j*, 2×10^7; *k*, 5×10^6. Sensitised LNC at a dose of 2×10^7 always restores first-set rejection and at a dose of 5×10^6 restored half the rats to first-set. First-set rejection can be restored to irradiated rats with 25–100-fold fewer sensitised LNC than naive LNC. Specificity of the increased potency of sensitised cells was confirmed by showing that 5×10^7 LNC from rats sensitised to DA (*l*) restored Lewis graft rejection to the same tempo as the same number of naive LNC (*g*).

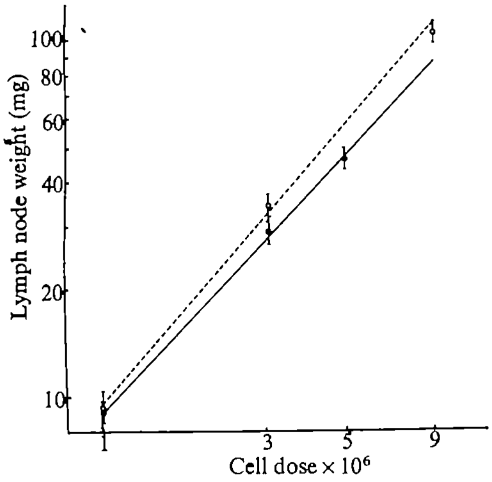

Fig. 2 Comparison of the GVH activity of LNC from normal and sensitised donors using the popliteal lymph node weight assay[17]. Varying numbers of LNC from PVG donors were injected into the right foot pad of groups of (DA×PVG) F_1 recipients matched for age and sex. Log lymph node weight (LNW) is plotted against log cell dose. Each point represents the arithmetic mean of at least 10 LNW. Vertical bars represent the s.e. The calculated regression lines are shown. ●, Response to PVG cells from normal donors (slope 1.0, correlation coefficient 0.94, s.d. of y 0.34). ○, Response to PVG cells from donors sensitised to DA alloantigen (slope 1.1, correlation coefficient 0.93, s.d. of y 0.41). The factor of immunisation at the lowest cell dose was 1.1 and the highest cell dose 1.3.

related to the cell dose (Fig. 1*e*, *f*). But, once this number was exceeded the response was not accelerated by increasing the number of adoptively transferred cells (Fig. 1*c*). 500×10^6 lymphocytes is only a fraction of the total lymphocyte complement of the intact rat[12]. Thus the quantitative increase in cell potency of 25–100-fold which occurs after sensitisation to antigens of the MHC is not detectable in the whole animal because it is already redundant in alloantigen sensitive cells. If, however, lymphocytes are adoptively transferred in limiting dilutions to an animal whose own cells have been destroyed by irradiation, the dramatic quantitative change in the lymphocyte pool of sensitised rats becomes obvious.

It has been shown that both GVH responses[13,14] and skin graft rejection[15] are mediated by pure populations of T cells. The most economical interpretation of our findings is that the clone of memory T cells which mediates graft rejection is functionally expanded 25–100-fold by prior immunisation. Failure of GVH assays to reflect this clonal expansion may indicate that the cells responsible for second set graft rejection are 'end' cells incapable of further proliferation.

Final proof that the increase in potency seen in the cells responsible for graft rejection is determined by antigens of the MHC and not minor histocompatability antigens awaits confirmation in congenic strains. Preliminary experiments indicate, however, that the potency of lymphocyte populations sensitised against multiple minor histocompatability antigens is more than an order of magnitude lower than that of cell populations sensitised against antigens of the MHC.

This dramatic effect of sensitisation on subsequent graft rejection has obvious relevance to clinical transplantation as well as to the fundamental biology of alloimmune responses. Investigations are at present in progress to determine the lifespan and distribution of the T cell responsible for these long term memory effects in the rat.

Sex steroid hormone regulation of IgA and IgG in rat uterine secretions

SEX steroid hormones may be important in regulating both the systemic and secretory humoral immune system and on the basis of this hypothesis, we have carried out a series of experiments to clarify the action of the sex hormones on the rat uterine immune system. We report here that the stage of the oestrous cycle and the administration of physiological amounts of oestradiol to castrate rats markedly influences the accumulation of immunoglobulin A (IgA) and G (IgG) in uterine secretions. IgG is maximal at pro-oestrus but barely detectable at oestrus, dioestrus, and following ovariectomy. IgA is highest at pro-oestrus, remains elevated at oestrus, but drops to low levels at dioestrus and following ovariectomy. Of the steroids tested only oestradiol stimulated the appearance of IgA and IgG. These findings indicate that oestradiol is important in influencing the presence of both immunoglobulins in the uterus.

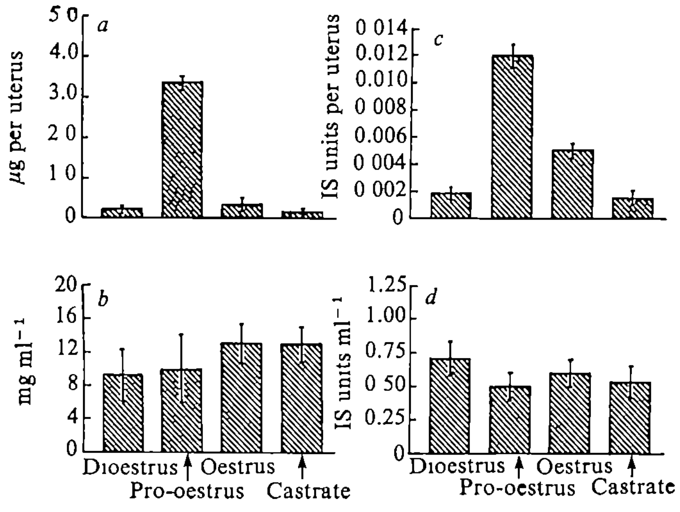
Our findings are of particular interest in the light of the fact that the use of the sex hormones to prevent conception and to reduce the discomfort of menopause has increased the incidence of a number of disorders in women[1–6], including alterations to the systemic immune system. Immunity to viral infections such as chicken pox, herpes simplex and rubella has been shown to be diminished among users of oral contraceptives[6], and women taking oestrogen have been estimated to have a 1.49- to 1.81-fold greater risk of infection than those not taking it. Similar results have been obtained with the administration of sex steroids to rats and mice[7,8]. Reports about the alteration in the local immune system in the female reproductive tract caused by sex steroids are somewhat conflicting. Although immune responsiveness and resistance to genital tract infection vary through the reproductive cycle (refs 9, 10 and 20), levels of IgA and IgG in cervical secretions have been reported by some to remain constant[9] and by others[11,12] to vary during the menstrual cycle. Furthermore, in the absence of apparent infection, oral contraceptives are reported to have altered antibodies in genital tract secretions, but whereas increased levels of immunoglobulins were reported with the use of combination oral contraceptives[9], sharp decreases were observed after the use of the sequential pill[11,12].

Adult female virgin Sprague–Dawley rats (Charles River Breeding Laboratories, Wilmington) maintained in constant-temperature rooms with 12-h intervals of light and darkness were used in this study. Vaginal smears were made daily and females were selected at given stages of the oestrous cycle after at least two consecutive normal 4-d cycles were observed. Ovariectomies were performed 10–15 d before each experiment. Following decapitation of the rats, uteri were perfused with sterile saline through the descending aorta to remove all blood from the vascular beds. Intact uteri were then removed and washed in 2–3 saline baths to eliminate adherent debris. A 26-gauge needle attached to a 1.0-ml tuberculin syringe containing 0.1 ml sterile saline was passed through the uterine wall at the ovarian end. As the saline was introduced into the lumen, a second syringe, with its needle inserted through the cervical musculature, was moved in synchrony to collect the uterine flushing. This procedure was repeated with the second uterine horn using the fluid recovered from the first. The fluid was centrifuged at 15,000*g* for 5 min, after which the supernatant was lyophilised and stored at −20 °C until assayed. Blood was collected immediately after decapitation and was allowed to clot for 30 min at room temperature. Following centrifugation at 15,000*g* for 5 min, serum was removed and frozen at −20 °C until assayed.

IgA and IgG were measured by radioimmunoassay. Rat IgG was purchased from Miles Laboratories; rabbit anti-rat heavy chain IgG antibody was a gift from Dr P. K. Chung (Miles Laboratories, Elkhart, Indiana); IgA-rich serum from rats with IR22 immunocytomas (IgA class) and goat anti-rat IgA (antiserum) prepared against this immunocytoma serum were gifts from Dr H. Bazin (Université Catholique de Louvain, Belgium). Anti-IgG and anti-IgA were coupled to cyanogen bromide-activated microcrystalline cellulose (Sigmacell, Sigma Chemicals, St Louis)[13]. The antigen components of the radioimmunoassay (rat IgG and rat IgA immunocytoma serum) were radiolabelled with ^{125}I using lactoperoxidase-bound Sepharose 4B (ref. 14). Uterine fluids were reconstituted with 50 μl of distilled water just before use and serum samples were diluted 200-fold before assay.

Figure 1*a* shows the levels of IgG in the uterine fluid of rats at various stages in the oestrous cycle and following castration. At pro-oestrus, the time in rats when plasma oestradiol is known to be highest[15], IgG levels were significantly higher (10–15-fold) than those of dioestrus, oestrus, and after castration. No significant differences were measured in serum IgG concentrations (Fig. 1*b*). The corresponding mean values of IgA are shown in Fig. 1*c*. As observed with IgG, IgA is highest at pro-oestrus, but also remains partially elevated at oestrus. Serum IgA levels in these animals show no significant variations (Fig. 1*d*).

Fig. 1 Immunoglobulin G (*a, b*) and A (*c, d*) levels in uterine secretions (*a, c*) and serum (*b, d*) of adult female rats. Values represent the mean ± s.e.m. of 5–8 rats per group. IgG values are expressed as μg per uterus; IgA results as immunocytoma serum (IS) units, where 1.0 IS unit is defined as a concentration of 1 mg of lyophilised immunocytoma serum ml^{-1} distilled water. Values of IgG and IgA at pro-oestrus and IgA at oestrus are significantly different from those measured during dioestrus and following castration ($P \leq 0.01$). No significant differences were measured in serum samples.



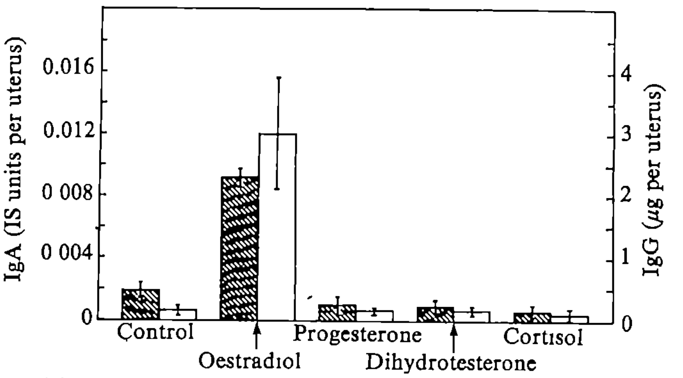


Fig. 2 IgA and IgG in uterine secretions of ovariectomised rats after three daily injections of steroids. Rats were injected with 0.1 ml of ethyl laurate containing either oestradiol (1.0 μg), progesterone (2,000 μg), dihydrotestosterone (1,000 μg) or cortisol (1,000 μg). Control groups received only ethyl laurate. Values represent the mean ± s.e.m. of 5 rats per group. The value for the oestradiol group was significantly higher ($P < 0.01$) than the values of the other groups. Hatched columns, IgA; plain columns, IgG.

Oestradiol, progesterone, cortisol and dihydrotestosterone were administered at concentrations known to elicit physiological responses in their respective target tissues. Time-course studies (not shown) indicated that the antibody response, although detectable at 1 and 2 d, was maximal after 3 d of repeated (daily) injections of steroid. Oestradiol administered daily to castrate rats elevated both uterine IgG and IgA (Fig. 2). Similar results were observed when oestradiol was administered to hypophysectomised rats. In contrast, however, progesterone, cortisol and dihydrotestosterone had no effect.

These results show that uterine IgG and IgA are under oestrogen control and differ from serum levels in the same animals. The data do not enable us to conclude whether the changes observed result from selective transport or *de novo* synthesis of antibodies in this organ. It is known that there are cells in the genital tract mucosa that produce both IgA and IgG. Immunofluorescent labelling of antibodies has led to the identification of subepithelial IgA and IgG plasma cells of the cervix and uterine endometrium[16,17]. In other studies, segments of uterine, cervical and vaginal tissues of the rabbit incorporate radioactive amino acids into IgA and IgG when incubated *in vitro* for 24 h (ref. 18). Similar techniques have also been used to demonstrate that these immunoglobulins are synthesised by the human cervix and vagina[19]. Further studies must be undertaken to determine which mechanism, transport or synthesis, is responsible for the oestrogen-influenced immunoglobulin accumulation in uterine secretions.

The investigation was supported in part by research grants AI 13541, AM 03535 and CA 17323 from the National Institutes of Health. We thank Elisabeth Hyde for cooperation in the preparation of this manuscript.

Chemical structure of attachment sites for viruses on human erythrocytes

ENCEPHALOMYOCARDITIS (EMC) virus attaches to erythrocytes from a variety of species through terminal sialic acid residues of the cell surface membrane (M. A. Angel and A.T.H.B., in preparation). Glycophorin, the major sialoglycoprotein of human erythrocytes has been identified as a receptor for influenza virus and some lectins[1]. In this report we present evidence that glycophorin is a human erythrocyte receptor for EMC virus also, and we have tentatively identified the location of a binding site for both EMC and influenza virus on glycophorin.

Glycophorin was prepared by the method of Marchesi and Andrews[1] from human type 0 erythrocytes, the cells used throughout these investigations. Electrophoresis of the glycophorin on 7.5% polyacrylamide gels in the presence of sodium dodecyl sulphate[2] gave a pattern (not shown) similar to that reported by Jackson *et al.*[3]—one major and a few minor components, possibly aggregates of glycophorin, were present, as revealed by staining either with Coomassie brilliant blue or with periodic acid–Schiff reagent.

Glycophorin was recognised as a receptor for influenza virus originally by its ability to inhibit virus haemagglutination[1,3]. We found that both EMC and influenza virus haemagglutination were severely inhibited to about the same extent by glycophorin (Table 1). Influenza virus haemagglutination is inhibited by sialoglycoproteins from many sources[6]. To determine whether or not the inhibitory action of glycophorin was a property of sialoglycoproteins in general, bovine submaxillary gland mucin (Worthington) and human serum glycoprotein (Mann Research) were tested, but neither inhibited EMC virus haemagglutination even at about 10 times the protein concentration at which glycophorin was effective (Table 1). In contrast, influenza virus haemagglutination was inhibited by mucin although not by human serum glycoprotein (Table 1).

Table 1 Effect of glycoproteins on agglutination of human erythrocytes by EMC and influenza viruses

Sialoglycoprotein	Protein concentration* (μg per well)	Haemagglutination titres (% of untreated control) EMC virus	Influenza virus
Human glycophorin	3.7	3	6
Bovine mucin	32.8	100	0.2
Human serum glycoprotein	43.8	100	100

Haemagglutination inhibition tests were performed using a microtitre system (Cooke Engineering) and, as diluent throughout, PBS–G–G, which comprised equal parts of 4.5% (w/v) glucose and PBS containing gelatin to 0.5% (w/v). Serial twofold dilutions of EMC or influenza virus, grown and purified as described previously[2,4], were made in 25-μl volumes and to each haemagglutination tray well was added either 25 μl of the sialoglycoprotein preparation or 25 μl of PBS–G–G in controls. After keeping the mixtures at 4 °C for 1 h, 50 μl of 0.1% (v/v) human erythrocytes were added to each well. The trays were maintained at least 5 h and usually overnight at 4 °C before haemagglutination titres were recorded. The reduction in haemagglutination caused by the sialoglycoprotein treatment is expressed as a percentage of the titre in untreated virus controls.

*Protein concentrations measured by the procedure of Lowry *et al.*[5].

Table 2 Inhibition of EMC virus attachment by glycophorin

(μg protein per sample)	% Attachment
0	75
0.4	35
0.8	23
8.0	0

To 10 μl of ^{3}H-amino acid-labelled EMC virus, prepared as already described[2] was added 10 μl of a glycophorin preparation (10 μl PBS in controls) and after 1 h at ambient temperature, 1 ml of 0.1% (v/v) human erythrocytes in PBS–G–G, (PBS–G–G alone in controls) was added. The samples were maintained a further 1 h at ambient temperature before centrifuging at 3000*g* for 5 min to collect the supernatant fluid. The erythrocytes (or deposits, where present in the absence of erythrocytes) were washed once in PBS–G–G before resuspending in 1 ml of PBS–G–G. After addition of 0.5 ml 30% H_2O_2 to all samples, to bleach the haemoglobin, the radioactive contents of erythrocytes (or deposits), supernatant fluid and wash, were measured in a Beckman LS 250 scintillation spectrometer. % Attachment represents the c.p.m. in the erythrocyte sample compared with the total c.p.m. recovered.

To test whether glycophorin inhibited attachment in addition to the subsequent agglutination step, ^{3}H-amino acid-labelled EMC virus, was mixed with various concentrations of glycophorin before measuring the ability of the virus to bind to erythrocytes. In the absence of glycophorin, 70–80% of the recovered radioactivity was bound by the erythrocytes whereas in the presence of glycophorin (0.8 μg glycophorin protein[5] per sample) this was reduced to 23% (Table 2). At higher glycophorin levels (8.0 μg protein per sample), attachment was virtually eliminated as revealed by recovery of background levels only of radioactivity in the erythrocytes.

Pretreatment of human erythrocytes with neuraminidase reduced EMC virus attachment to about 15% of that of untreated controls and usually abolished haemagglutination by EMC or influenza virus (Table 3). Neuraminidase, previously heated at 100 °C for 10 min, had no such effect, showing that this was an efficient means for inactivating the enzyme. If glycophorin is the molecule to which EMC virus binds on the erythrocyte surface, neuraminidase treatment of glycophorin should abolish its ability to inhibit attachment of EMC virus. This was found to be the case; glycophorin (0.8 μg protein per sample) pretreated with neuraminidase (0.5 units per sample) had almost no inhibitory effect against EMC virus, attachment being 86% of that in the absence of glycophorin (not shown). The loss of inhibitory properties did not result from the heating procedure required to destroy the neuraminidase since glycophorin, heated but not treated with enzyme, reduced EMC virus attachment to 8% and thus showed enhanced inhibitory properties compared with unheated glycophorin at the same concentration (Table 2).

To determine how glycophorin interfered with virus attachment, 25 μl of ^{3}H-labelled EMC virus was mixed with 25 μl of glycophorin, bovine submaxillary gland mucin or human serum glycoprotein (each containing 100 μg protein), or with phosphate-buffered saline (PBS), and after incubating at ambient temperature for 60 min, each sample was examined by sucrose gradient sedimentation. The samples incubated with mucin, human serum glycoprotein or PBS all showed a single peak of radioactivity at a position characteristic of EMC virus, whereas most of the radioactivity in the glycophorin sample sedimented to the bottom of the tube (Fig. 1). A similar result was obtained when each sialoglycoprotein sample was adjusted to the same sialic acid content (12 μg sialic acid per sample as determined by the thiobartituric acid procedure of Warren[7]) rather than the

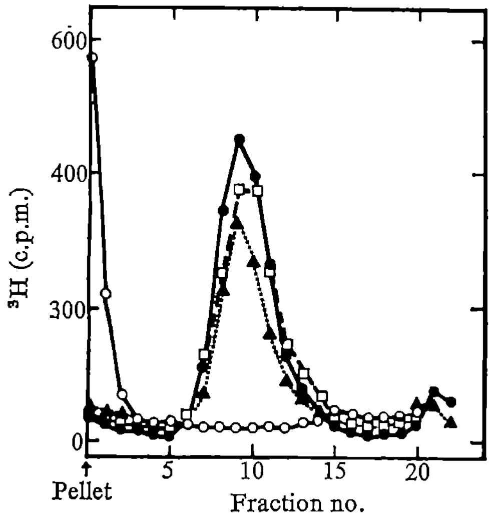

Fig. 1 Rate of zonal sedimentation of ^{3}H-labelled EMC virus incubated for 60 min at ambient temperature with glycophorin (○), mucin (□), humanse rum glycoprotein (●) or PBS (▲) before analysis on 10–30% sucrose gradients containing 0.1 M NaCl and 0.02 M phosphate buffer, pH 8.0 in a Spinco SW 50.1 rotor at 50,000 r.p.m. for 30 min. Direction of sedimentation is from right to left.

same protein content. These results suggest that glycophorin, unlike mucin and human serum glycoprotein, attaches to EMC virus-forming aggregates and in so doing inhibits attachment of virus to cells. However, the aggregates are apparently not sufficiently large to sediment with erythrocytes in the conditions of low-speed centrifugation used to measure attachment of virus to cells.

The work of Marchesi and colleagues[3,8] suggests that trypsin treatment of intact human erythrocytes releases from glycophorin amino acids 1–39, numbered from the N terminus, and leaves projecting from the cell surface a short sequence containing about 25 amino acids beyond which the glycophorin is embedded in the cell surface membrane. We found that trypsin-treated erythrocytes consistently gave haemagglutination titres equal to, or up to threefold dilutions higher for both EMC and influenza virus and bound about the same amount of ^{3}H-labelled EMC virus, compared with controls incubated in the absence of trypsin; typical results are given in Table 3. This suggests that both EMC and influenza virus can attach to the 25 amino acid segment of glycophorin remaining exposed on the cell surface after trypsin treatment. The results do not exclude the possibility, suggested for influenza virus from the work of Marchesi and colleagues[3], that virus attachment sites are also present in the 39 amino acids released by trypsin.

Table 3 Agglutination of enzyme-treated erythrocytes by EMC and influenza viruses

	% of untreated controls		
	Haemagglutination titres		Attachment of ^{3}H-EMC virus
Enzyme treatment	EMC virus	Influenza virus	
Neuraminidase	0	0.3	15.0
Trypsin	200	400	98.0
Trypsin then neuraminidase	2.3	0.3	17.6
Neuraminidase then trypsin	3.1	1.0	ND*

Preparations of 0.1% (v/v) human erythrocytes were incubated at 37 °C for 30 min with 1 mg ml^{-1} trypsin (Worthington) or with 50 units per ml *Vibrio cholerae* neuraminidase (Calbiochem). The enzymes were removed by washing before applying the second enzyme treatment and/or using for haemagglutination or virus attachment studies as described in Table 2.

*ND, Not determined.

The ability of trypsin treated cells to bind ^{3}H-labelled EMC virus or to be agglutinated by either EMC or influenza virus was greatly reduced if the cells were subjected to further incubation with neuraminidase (Table 3). A similar reduction in haemagglutination titre was observed for cells treated with neuraminidase before trypsin (Table 3). These results suggest that sialic acid residues in the fragment remaining with the cells after trypsin treatment are involved in attachment of both EMC and influenza virus to human erythrocytes. Only three amino acids in this fragment have sialic acid attached: serine at positions 44 and 47 and threonine in position 50 (ref. 8). We conclude, therefore, that one or more of these three sialic acid groupings on glycophorin is involved in the binding of EMC or influenza virus by human erythrocytes.

We thank Drs F. Kingsley Sanders, Ellen M. Duffy and Robert A. Good for their interest and encouragement and Dr R. Peterson for valuable advice. We thank Dr R. M. Krug for providing the WSN strain of influenza virus and Marilyn A. Angel for growing and purifying the EMC virus and for technical assistance. The work was supported in part by US NCI grant CA-08748, the Fund for the Advanced Study of Cancer and the Zelda R. Weinbtraub Cancer Fund.

Synthesis of low molecular weight inhibitor of protein synthesis with enzyme from interferon-treated cells

PROTEIN synthesis in cell-free systems from mouse L cells pretreated with the antiviral agent interferon[1] shows an enhanced sensitivity to inhibition by double-stranded RNA (dsRNA) (refs 2–4). The inhibition of protein synthesis is dependent on incubation with ATP as well as dsRNA and we and others have reported a dsRNA-dependent protein kinase activity(s) in extracts from interferon-treated cells[5–8]. The possible involvement of a viral dsRNA-mediated inhibition of protein synthesis in the sequence of events following virus infection in intact, interferon-treated cells has been discussed previously[2,4]. The situation with extracts from interferon-treated cells[5–8] is reminiscent of that in rabbit reticulocyte lysates in which phosphorylation of an initiation factor by a protein kinase has been implicated in the inhibition of protein synthesis in a variety of conditions including the presence of dsRNA[9–11]. In the interferon-treated L-cell system, however, in addition to the kinase, a heat-stable, low molecular weight inhibitor (LMW inhibitor) of protein synthesis is formed on incubation with ATP and dsRNA (ref. 6). It remained possible from our previous work[6], that the LMW inhibitor might be a small phosphorylated peptide product of the dsRNA-dependent kinase. We show here that this is not the case. In addition, we show that the enzyme responsible for the synthesis of the LMW inhibitor will bind to a column of dsRNA attached to a solid support. It can be eluted in high salt but is relatively unstable in this form. We have used the highly-purified enzyme in its stable column-bound state to synthesise and radioactively label the LMW inhibitor. This synthesis, the partial purification of the inhibitor and its activity in the inhibition of protein synthesis in cell-free systems from L cells and rabbit reticulocytes, are reported here. A more detailed characterisation of the inhibitor is described in the accompanying paper[13].

The enzyme(s) responsible for the synthesis of the LMW inhibitor (inhibitory enzyme) binds to dsRNA, so chromatography on columns of poly(I)·poly(C) bound to Sepharose (poly IC-Sepharose) (refs 14, 15) were used to purify this enzyme(s) and the dsRNA-dependent protein kinase(s). (Prelininary results indicate that the two activities can be separated, A.G.H., unpublished). On passage of a post-ribosomal supernatant fraction from interferon-treated cells (interferon cell sap) through such a column, the inhibitory enzyme and kinase activities were retained. The inhibitory enzyme was recovered on elution with high salt (1 M KCl) at a purification of more than 1,000-fold (a minimum figure is given since the amount of protein in the eluate was too low to be measured). The 1 M KCl eluate contained all of the recoverable inhibitory enzyme activity (⩾25%), assayed either by the formation of the LMW inhibitor on incubation with ATP and dsRNA (refs 5,6), or by its addition with dsRNA to an L cell-free system[4,9]. No such activity was detected with corresponding control cell material.

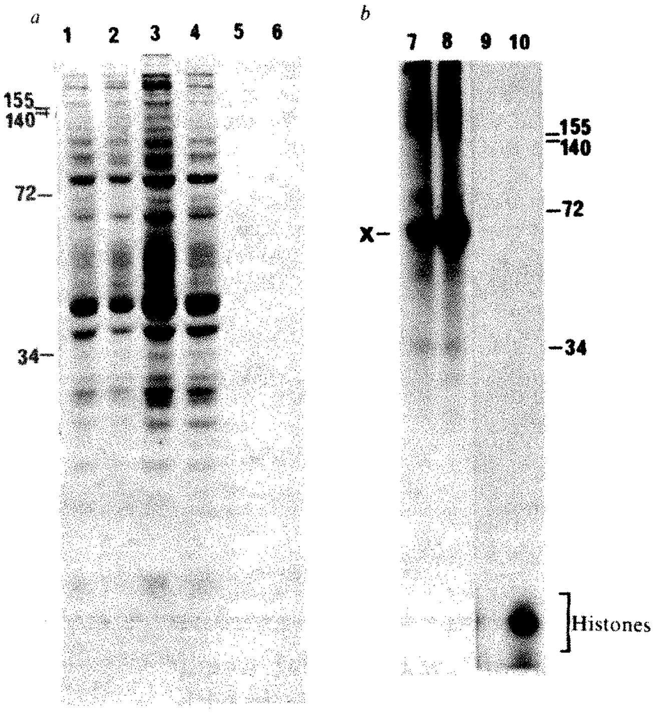

Fig. 1 Chromatography of interferon and control cell saps on poly IC-Sepharose: electrophoretic analysis on polyacrylamide (10%) slab gels containing sodium dodecyl sulphate (SDS) (refs 16, 17). Interferon or control cell caps (50 µl) were passed through columns of poly IC-Sepharose (50 µl) equilibrated with dialysis buffer containing glycerol (DBG: 10 mM HEPES, *p*H 7.5, 90 mM KCl, 1.5 mM magnesium acetate, 7 mM 2-mercaptoethanol and 20% glycerol, v/v). The columns were extensively washed with DBG and the starting material, that retained on the column and the initial pass-through, were analysed for protein and protein kinase activity. *a*, Gel stained for protein: control (1) and interferon (2) cell sap (2 µl), control (3) and interferon (4) pass-through (equivalent to 4 µl of cell sap). For protein retained on the column, the control (5) and interferon (6)-poly IC-Sepharose were heated (95 °C, 10 min) in sample buffer containing SDS (ref. 16), centrifuged and supernatant equivalent to 50 µl of cell sap applied to the gel. *b*, Kinase activity: an autoradiograph of a stained, dried gel is shown. Control (7) and interferon (8) poly IC-Sepharose incubated 60 min at 30 °C with 0.15 mM γ-^{32}P-ATP (7.1 Ci mmol^{-1}, Radiochemical Centre, Amersham) in DBG containing 10 mM magnesium acetate. Phosphorylation of histone: control (9) and interferon (10)-poly IC-Sepharose samples were incubated (60 min, 30 °C) with 1 mM ATP. Calf thymus histone (type IIA, Sigma, 1 mg ml^{-1}) and γ-^{32}P-ATP (0.15 mM, as above) were added and incubation continued for 30 min. The poly IC-Sepharose samples (7–10) were heated (95 °C, 10 min) in sample buffer containing SDS and supernatants equivalent to 7 µl of cell sap applied to the gel. The numbers to the left and right give the molecular weights in thousands of the major reovirus polypeptides λ1, λ2, µ2 and σ3 (ref. 18). The phosphorylated polypeptide band X corresponds to that previously observed on incubation of interferon cell sap with γ-^{32}P-ATP and dsRNA (Figs 1 and 4, ref. 6). Interferon treatment of mouse L cells with low doses (5 to 20 effective units per ml) of highly-purified mouse interferon (⩾5×10^7 units per mg protein), the preparation of cell extracts and of interferon and control cell saps were as described previously[2–4].

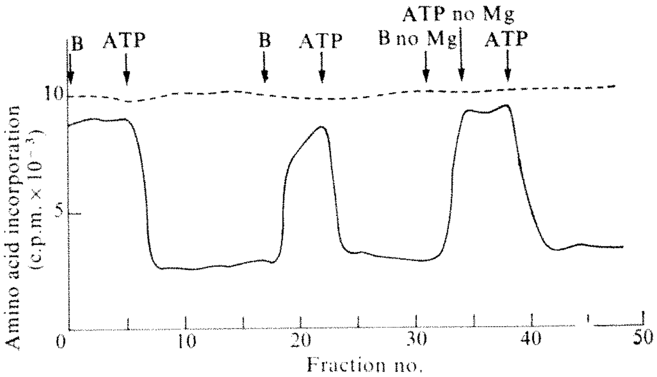

Fig. 2 Synthesis of the LMW inhibitor. Control (- - - - -) and interferon (————) poly IC-Sepharose columns (250 µl) were prepared as in Fig. 1, washed extensively with DBG and incubated at 30 °C in the different conditions indicated (arrows). Abbreviations: B = DBG; ATP = DBG plus 1 mM ATP; B no Mg = DBG minus magnesium acetate; ATP no Mg = DBG plus 1 mM ATP minus magnesium acetate. For each set of conditions the columns were stopped and incubated for 20 min at 30 °C before collection of each 300-µl fraction. Samples diluted 50-fold were assayed for their inhibitory activity on cell-free protein synthesis[4–6,17]. The inhibitory activity of the samples was unaffected by heating at 95 °C for 5 min (data not shown). The ordinate gives the incorporation (c.p.m. per 10 µl sample) of a ^{14}C-amino acid mixture into hot trichloroacetic acid-insoluble polypeptide in response to encephalomyocarditis virus RNA (EMC RNA) in an L cell-free system[4–6,17].

Although it was not possible to detect protein on the interferon and control poly IC-Sepharose columns (prepared as in Fig. 1) by conventional techniques (Fig. 1*a*), when these columns were incubated with γ-^{32}P-ATP phosphorylated polypeptides were detected (Fig. 1*b*). The extent of phosphorylation of a polypeptide of approximately 60,000 in apparent molecular weight (band X, Fig. 1*b*) was the most striking difference between the interferon and control preparations. By analogy with the reticulocyte lysate system[10], this phosphorylation is thought to represent autophosphorylation of the dsRNA-dependent protein kinase[6]. Bands Y and Z reported previously for interferon cell sap (Figs 1 and 4, ref. 6) were not observed here, presumably because the appropriate substrates were not retained on the column. The protein kinase activity(s) of the interferon and control preparations were further investigated by incubation of interferon and control poly IC-Sepharose which had been pre-incubated with unlabelled ATP, with additional histone and γ-^{32}P-ATP. In these conditions histone was phosphorylated with the interferon but not the control poly IC-Sepharose (Fig. 1*b*, channels 9 and 10).

The inhibitory enzyme bound to poly IC-Sepharose was active in the synthesis of the LMW inhibitor. The formation of the inhibitor was dependent on Mg^{2+} and could be controlled by the provision or withdrawal of ATP (Fig. 2). No inhibitor was formed with corresponding control material (Fig. 2). The requirement for ATP suggested that it might form an integral part of the LMW inhibitor, so an attempt was made to label the LMW inhibitor by incubation of the column-bound enzyme with ^{3}H-ATP. In these conditions label (^{3}H) was incorporated into material which co-purified with the LMW inhibitor on chromatography on DEAE–cellulose and Sephadex G-25 (Fig. 3). The behaviour of this column-syn hesised inhibitor on the latter was, incidentally, identical to that previously described for the LMW inhibitor made by incubation of crude interferon cell sap with ATP and dsRNA, being retarded on the column but eluting before marker ATP (Fig. 3, ref. 6). Further evidence that ATP forms an integral part of the inhibitory molecule is presented in the accompanying paper[13].

As here we seemed to be dealing with an inhibitor of a type not previously characterised, it was of interest to see if it had activity in different cell-free systems. The LMW inhibitor, in fact, showed similar activity in the inhibition of endogenous or EMC RNA-directed protein synthesis in the rabbit reticulocyte lysate system, to that observed in the L cell-free system (Fig. 4). The kinetics of inhibition in both systems with the LMW inhibitor were similar to those observed with dsRNA or the haem-controlled repressor in the reticulocyte lysate[9–12,19]. In each case there was a lag of 10–15 min before onset of the inhibition (Fig. 4). In view of this and the effectiveness of the LMW inhibitor at subnanomolar concentrations[13], it remains possible that the LMW inhibitor is not directly inhibitory but that it, in turn, regulates the formation of an inhibitor(s) or subsequent inhibitory events.

We have shown here that the enzyme(s) responsible for the synthesis of the LMW inhibitor and a protein kinase(s) are retained on poly IC-Sepharose. The poly IC-Sepharose column, therefore, provides a possible basis for their separation, characterisation and the determination of their respective roles in the inhibitory process(s). Meanwhile the column technique has provided a simple, convenient method for the synthesis of the LMW inhibitor. The availability of radioactively-labelled inhibitor synthesised in this way has considerably facilitated its initial characterisation[13] and should prove invaluable in the elucidation of its structure, mechanism of action and role in the inhibition of cell-free protein synthesis by dsRNA.

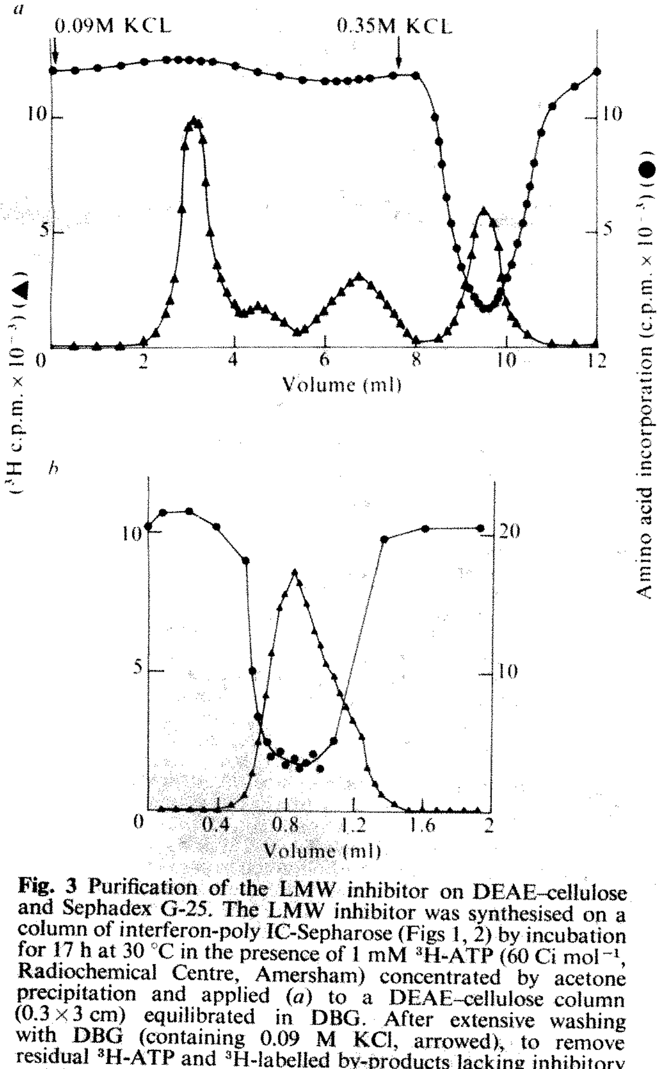

Fig. 3 Purification of the LMW inhibitor on DEAE–cellulose and Sephadex G-25. The LMW inhibitor was synthesised on a column of interferon-poly IC-Sepharose (Figs 1, 2) by incubation for 17 h at 30 °C in the presence of 1 mM ^{3}H-ATP (60 Ci mol^{-1}, Radiochemical Centre, Amersham) concentrated by acetone precipitation and applied (*a*) to a DEAE–cellulose column (0.3 × 3 cm) equilibrated in DBG. After extensive washing with DBG (containing 0.09 M KCl, arrowed), to remove residual ^{3}H-ATP and ^{3}H-labelled by-products lacking inhibitory activity, the LMW inhibitor was eluted at higher salt (0.35 M KCl). Peak fractions containing the LMW inhibitor were pooled, concentrated by acetone precipitation and chromatographed (*b*) on Sephadex G-25 (fine) as described previously[6]. In these conditions excluded material elutes between 0.3 and 0.5 ml and ATP between 0.9 and 1.5 ml (compare with Fig. 3, ref. 6). Samples (at a final dilution of 2,500-fold in *a* and 10,000-fold in *b*) were assayed for inhibitory activity on cell-free protein synthesis[4–6]. The right hand ordinates give the incorporation of ^{14}C-amino acids in an L cell-free system as in Fig. 2 (●). Those on the left show the radioactivity in each fraction (^{3}H c.p.m. per 5-μl sample) originating from the ^{3}H-ATP (▲).

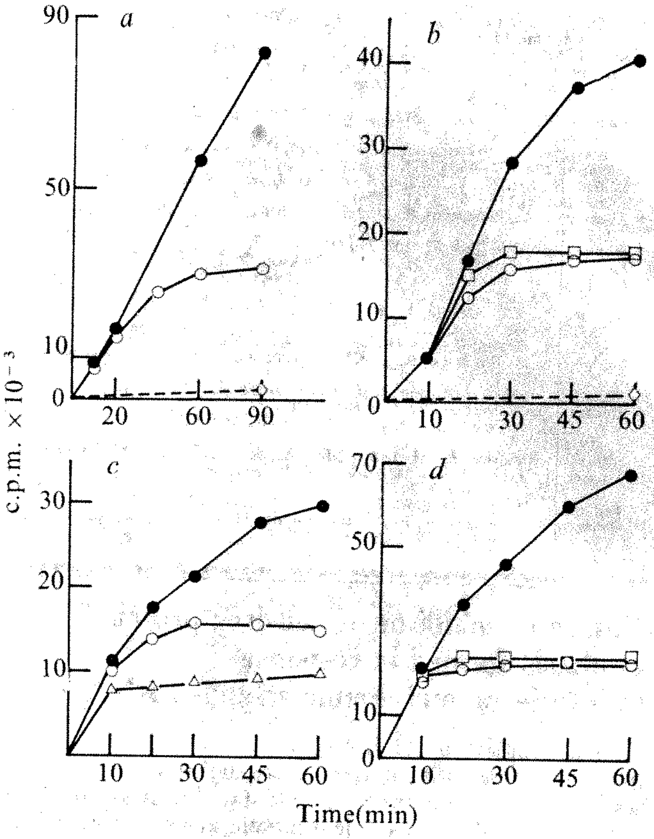

Fig. 4 Assay of the LMW inhibitor in cell-free systems from mouse L cells and rabbit reticulocytes: comparison with dsRNA and the haem-controlled repressor (HCR) (refs 5–8, 19). *a*, *b*, Translation of EMC RNA in the absence (●) or presence of the LMW inhibitor (○) or poly(I)·poly(C) (□) in cell-free systems using: *a*, preincubated and dialysed S10 from mouse L cells[17]. *b*, A micrococcal nuclease-treated rabbit reticulocyte lysate[20]. There was negligible incorporation in the absence of EMC RNA (◇). *c* and *d*, Amino acid incorporation in the absence (●) or presence of the LMW inhibitor (○), poly(I)·poly(C) (□) or HCR (△) in an untreated rabbit reticulocyte lysate system in the absence (*c*) or presence (*d*) of EMC RNA (16 μg ml^{-1}). Preparation of the cell-free systems and the incubation conditions used were based on those described before[17,20,21]. Incubations were at 30 °C for the times indicated (abscissa). The ordinates give the incorporation (c.p.m. per 3 μl sample) of ^{35}S-methionine (200–500 Ci mmol^{-1}, Radiochemical Centre, Amersham) into hot trichloroacetic acid-insoluble polypeptide[17]. The same concentration (1 μl of a 300-fold dilution per 12.5 μl assay) of the same preparation of the LMW inhibitor purified on DEAE–cellulose was used in all cases. (Its inhibitory effect in the reticulocyte lysate was not due to the carryover of poly(I)·poly(C) from the Sepharose column. Any such material was removed by the DEAE–cellulose step[5]. In addition, similar results have been obtained with material further purified on Sephadex G-25 (Fig. 3*b*) and by paper electrophoresis[13].) Poly(I)·poly(C) (Sigma) was added to a final concentration of 100 ng ml^{-1}. The HCR was prepared and used as before[21]. It and the rabbit reticulocyte lysates were gifts of M. J. Clemens.

A.G.H. was the recipient of a Wellcome Trust Fellowship.

Nature of inhibitor of cell-free protein synthesis formed in response to interferon and double-stranded RNA

PROTEIN synthesis in cell-free systems from mouse L-cells pretreated with the antiviral agent interferon[1] shows an enhanced sensitivity to inhibition by double-stranded RNA (dsRNA) (refs 2–4). A dsRNA-dependent protein kinase[5–7] and a heat-stable, low-molecular-weight inhibitor (LMW inhibitor) of protein synthesis which is formed in such systems on incubation with ATP and dsRNA (ref. 7), seem likely to be involved. We have shown[8] that the LMW inhibitor can be conveniently synthesised using a highly-purified enzyme fraction from interferon-treated cells bound to dsRNA on an inert support. Here we report its partial characterisation.

Throughout this work the LMW inhibitor was assayed by its ability to inhibit the translation of encephalomyocarditis virus RNA (EMC RNA) in cell-free systems from mouse L-cells[4,7]. It was synthesised in the presence of ^{3}H-ATP or ATP labelled with ^{32}P in the α or γ position using an enzyme fraction bound to a poly(I)·poly(C)-Sepharose column[8] or, as previously, by incubation of crude cell sap from interferon-treated cells with ATP and dsRNA (refs 4, 7). After chromatography on DEAE–cellulose to remove residual ATP (ref. 8), the different inhibitor preparations were analysed by electrophoresis on paper at *p*H 3.5 (Fig. 1). The inhibitory activity eluted as a single peak (Fig. 1*a*) coincident with the major peaks of ^{3}H, α- or γ-^{32}P (Fig. 1*a–c*). This was true for the intrinsic inhibitory activity of the radioactively-labelled, column-synthesised material or for the unlabelled inhibitor made in crude extracts. It seems, therefore, that the inhibitor synthesised using the column method is not an artefact of the column procedure, but is identical to that formed in response to dsRNA in cell-free systems from interferon-treated cells. Moreover it can be labelled with ^{3}H-ATP or with α- or γ-^{32}P-ATP. The column-bound enzyme[8] is extensively washed before use in the synthesis of the inhibitor. It seems unlikely, therefore, that any low molecular weight component other than ATP (as much as 20% of which is consumed in the formation of the inhibitor) is required in significant amounts for its synthesis.

It is possible to calculate the concentration of AMP in the purified LMW inhibitor preparations from the observed ^{3}H or α-^{32}P counts and the known specific activity of the radioactive ATP used in its synthesis on the column[8]. In four different preparations the dilution of inhibitor required to produce a 50% inhibition of protein synthesis in the cell-free system corresponded to an AMP concentration of 0.3 to 1 nM (Fig. 2). Accepting the intrinsic variability of the cell-free assay and that the inhibitor preparations were not completely pure (contamination ≤ 30%, I.M.K and R.E.B, unpublished results), the correspondence between the four preparations, two labelled with ^{3}H-ATP and two with α-^{32}P-ATP, is remarkably good. Accordingly these data, together with those presented in Fig. 1 and the accompanying paper[8], strongly suggest that ATP is a substrate in the synthesis of the inhibitor and forms an integral part of the biologically active molecule. Further evidence for this and a partial characterisation of the inhibitor was provided by the experiments described in Fig. 3.

Inhibitor was synthesised in the presence of α-^{32}P-ATP, chromatographed on DEAE–cellulose[8] and subjected to enzy-

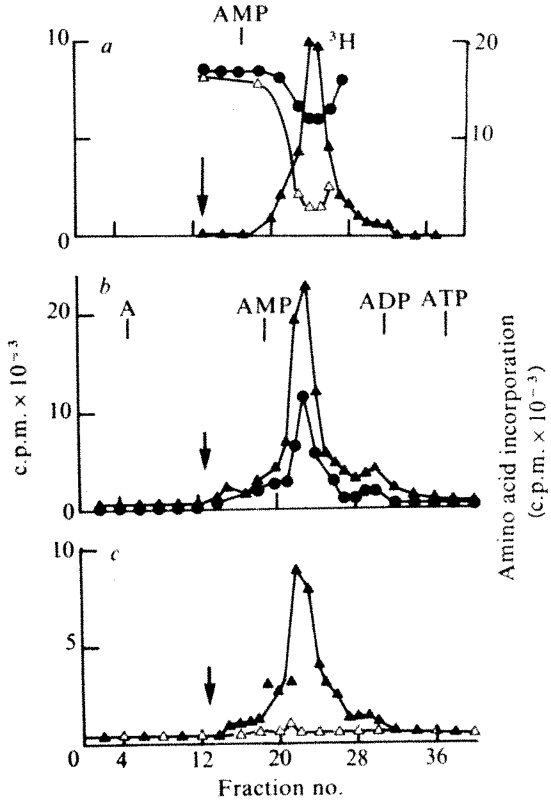

Fig. 1 Electrophoretic analysis of the LMW inhibitor. The LMW inhibitor was synthesised in the presence of ^{3}H-ATP, α- or γ-^{32}P-ATP with an enzyme fraction bound to a column[8], or by incubation of unlabelled ATP with cell sap from interferon-treated cells and dsRNA (refs 4, 7). After chromatography on DEAE–cellulose[8], peak fractions were subjected to electrophoresis on Whatman 3MM paper in pyridine–acetic acid–water (1:10:989, v/v/v) *p*H 3.5 at 4,000 V for 45 min. The paper was dried, cut and 1-cm sections either eluted for assay of inhibitory activity in the cell-free system or counted for radioactivity. In each case the arrow indicates the origin with the cathode to the left. The position to which unlabelled A, AMP, ADP and ATP markers migrated is indicated. (In this system the inhibitor is easily distinguished from any residual ATP). *a*, Inhibitor synthesised in the presence of ^{3}H-ATP (ref. 8) or as previously with cold ATP (refs 4, 7) were electrophoresed in parallel and analysed for radioactivity: (▲, ^{3}H, left-hand ordinate) and for inhibitory activity in the cell-free system. The right-hand ordinate shows the incorporation of a ^{14}C-amino acid mixture into hot trichloroacetic acid-insoluble polypeptide in response to EMC RNA in a cell-free system from control mouse L cells[4,7] (c.p.m. per 10-µl sample) assayed in the presence of eluted material at an overall dilution of 100 (Δ) or 10^{3}-fold (●). There was no inhibition with corresponding control material. *b*, Inhibitor preparations synthesised by the column method[8] in the presence of ●, ^{3}H-ATP and ▲, α-^{32}P-ATP electrophoresed in parallel. *c*, Distribution of ^{32}P in interferon (▲) and corresponding control (Δ) preparations synthesised in the presence of γ-^{32}P-ATP. For the control, interferon cell sap was replaced by control cell sap in the synthetic procedure described in the accompanying paper[8]. Similar controls have yielded similar results with ^{3}H-ATP and α-^{32}P-ATP. For inhibitor synthesised in the presence of ^{3}H-ATP, α- or γ-^{32}P-ATP the intrinsic inhibitory activity migrated with the major peak of radioactivity (data not shown). The ^{3}H-ATP (27 Ci mmol^{-1}) and α and γ-^{32}P-ATP (5 to 15 Ci mmol^{-1}) were obtained from the Radiochemical Centre, Amersham).

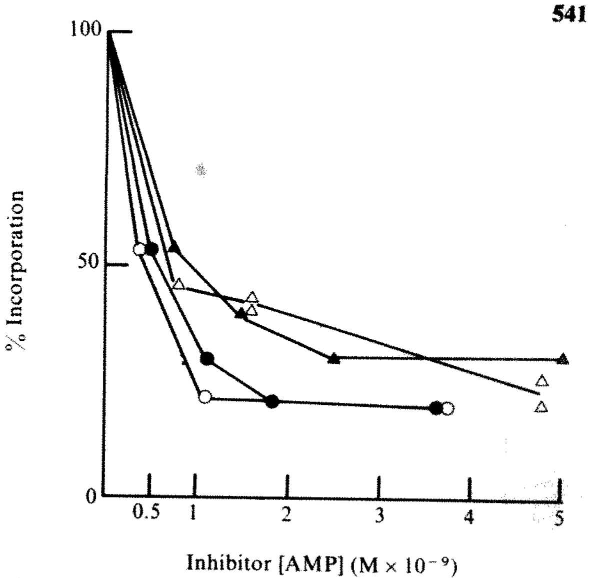

Fig. 2 Concentration of AMP in the inhibitor preparations for 50% inhibition of protein synthesis in the cell-free system. The LMW inhibitor was synthesised by the column method[8] in the presence of 1 mM ATP in a total 'column volume' of 0.15 to 0.9 ml. Radioactive ATP (as in Fig. 1) was added as follows: ^{3}H-ATP to a final specific activity of 145 (○) and 120 (●) Ci mol^{-1}, α-^{32}P-ATP to a final specific activity of 18 (△) and 135 (▲) Ci mol^{-1}. After chromatography on DEAE–cellulose to remove residual ATP (ref. 8) samples containing ^{3}H or ^{32}P were either dried on to glass fibre filters and counted in a Beckman scintillation counter using a toluene-based scintillation fluid with efficiencies of 30% and ⩾ 90% respectively, or assayed at suitable dilution (1 µl of a 1,000–20,000-fold dilution per 12.5-µl assay) for inhibitory activity in the cell-free system. The concentration of AMP in the cell-free system assay (abscissa) was calculated from the known specific activity, the counts in the sample and the dilution used in the assay. Inhibitory activity in the cell-free system was assayed as described in Fig. 1: the ^{14}C-amino acid incorporation for assays in the presence of different dilutions of the inhibitor is expressed as a percentage of the control (no inhibitor) value which varied from 8,000 to 20,000 c.p.m. per 10 µl sample in different experiments.

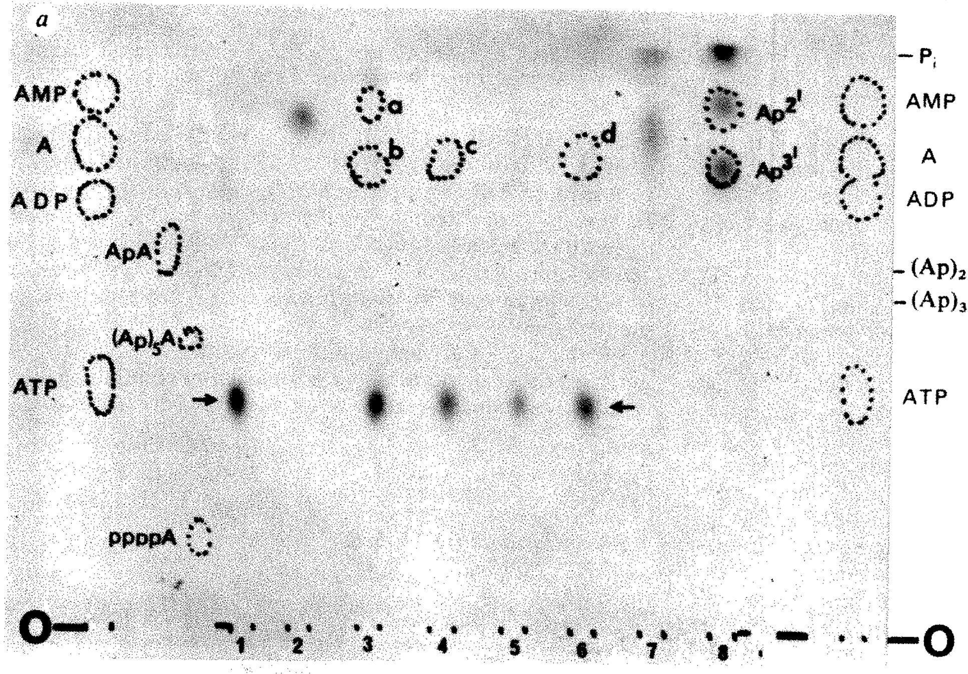
matic and alkaline digestion. The products were analysed by thin-layer chromatography on polyethyleneimine (PEI) cellulose[9] (Fig. 3*a*). Destruction of inhibitory activity was assayed in the cell-free system[4,7] (Fig. 3*b*). On chromatography the inhibitory activity migrated with the major radioactive component (arrowed Fig. 3*a*). From Fig. 3 it can be seen that the inhibitor is sensitive to digestion with snake venom phosphodiesterase (SVPD), bacterial alkaline phosphatase (BAP) and alkali, but is resistant to micrococcal nuclease, and to nucleases P1, T2 and U2 in conditions of complete digestion of ApA (Fig. 3*a*), (Ap)$_2$A or (Ap)$_5$A included as internal markers. An identical spectrum of resistance and sensitivity to these agents has been obtained with inhibitor labelled with ^{3}H-ATP or γ-^{32}P-ATP and with unlabelled inhibitor formed in crude interferon cell sap[4,7]. (In the latter two cases sensitivity to T2 and U2 has not been tested.) Radioactivity (major spot, arrowed Fig. 3*a*) and inhibitory activity were lost in parallel on partial digestion with alkali or BAP. With γ-^{32}P-ATP-labelled inhibitor, digestion with BAP alone liberated all of the ^{32}P as inorganic phosphate (P$_i$) with corresponding loss of



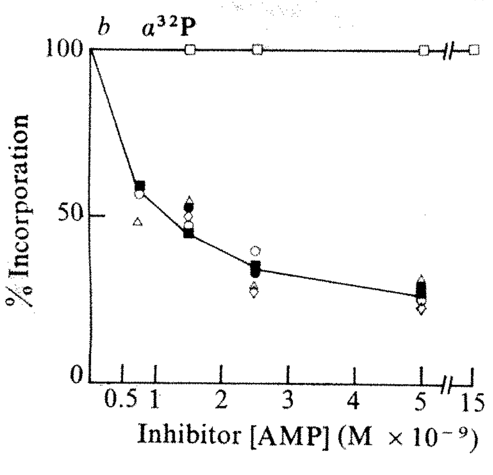


Fig. 3 Enzyme susceptibility of the LMW inhibitor. The LMW inhibitor was synthesised in the presence of α-^{32}P-ATP by the column method and chromatographed on DEAE-cellulose to remove residual ATP (ref. 8). It was subjected to enzymatic and alkali digestion followed either by *a*, chromatographic analysis in 0.75 M potassium phosphate, *p*H 3.4, on thin-layer plates of PEI cellulose[9] (Machery Nagel, Polygram Cel 300 PEI, Camlab), or *b*, assay for inhibitory activity in the cell-free system as described in Figs 1 and 2. The ordinate and abscissa (*b*) were as described in Fig. 2. *a*, 1, Untreated inhibitor; 2–8, inhibitor after digestion with SVPD, P1, T2, micrococcal and U2 nucleases, BAP and BAP followed by alkali, respectively. *b*, ■, Untreated inhibitor; △, ○, ●, ◇, inhibitor after digestion with P1, T2, U2 and micrococcal nucleases, respectively; □, inhibitor after digestion with SVPD, BAP or BAP plus alkali. (Similar results were obtained for biological activity after digestion with alkali alone, data not shown.) Enzyme digestions were carried out in 5–20 µl reactions for 1–6 h at 37 °C in the conditions described by Brownlee[10] (for T2, U2 and micrococcal nucleases, SVPD and BAP) and Rose[11] (for P1). Alkali digestion was for 17 h in 0.3 M KOH. An autoradiograph of the dried plate is shown (*a*). In *a*, 3, 4 and 6 an approximately 100-fold excess of unlabelled ApA was added to the α-^{32}P-labelled inhibitor before digestion to provide a positive control showing enzyme activity. Spots a, b, c and d were detected under ultraviolet light and are the digestion products of the ApA—a, p(5′)A; b, A; c, e, A and A(3′)p. Digestion was without effect on the inhibitor (arrowed) here or in parallel experiments in which the same digestions were carried out in the absence of ApA (data not shown). The slight variation in the intensity of the inhibitor spot (arrowed) reflects variation in the amounts loaded. The optical density markers (dotted circles) A, AMP, ADP, ATP, Ap (mixture of 2′ and 3′), A(3′)p, ApA and p$_4$A were from Sigma and (Ap($_2$A and (Ap)$_3$A from Boehringer. (Ap)$_5$A and micrococcal nuclease were from PL Biochemicals. The SVPD and P1 (from *Penicillium* citrinum), T2 (RNase T2 from *Aspergillus*)[10] and U2 (RNase U2 from *Ustilago*)[10] nucleases were gifts of Dr Beverley Griffin. BAP was 'BAPF' from Worthington.

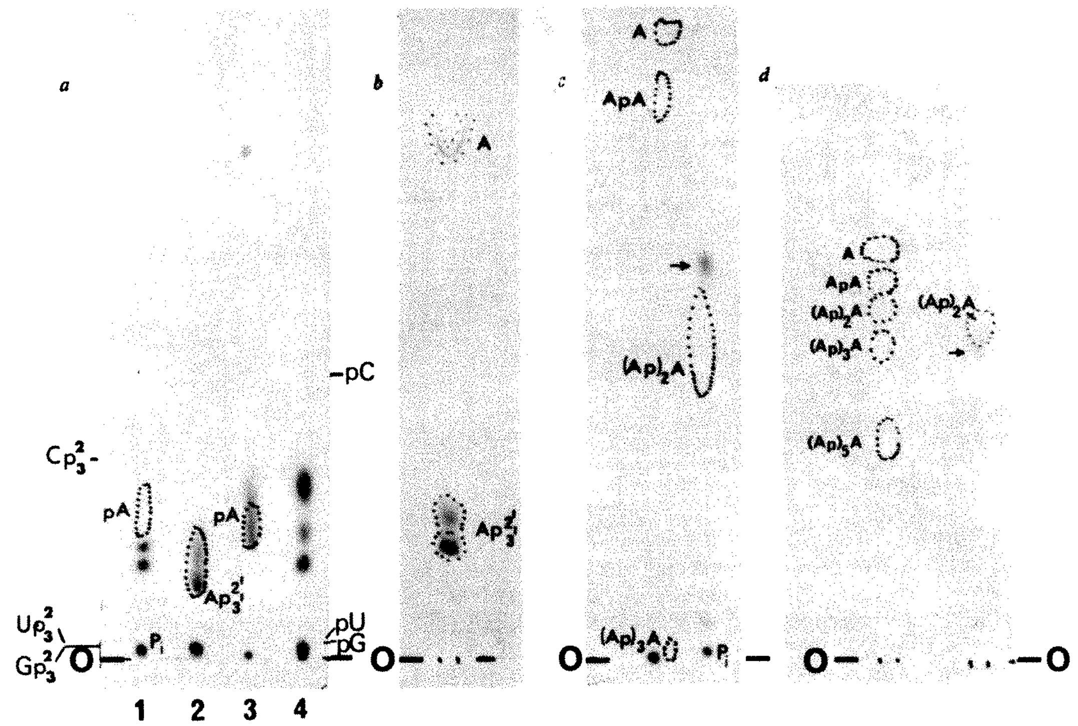

Fig. 4 Analysis of the products of SVPD, BAP and BAP followed by alkali digestion of the ^3H or α-^{32}P-labelled inhibitor. LMW inhibitor was prepared and subjected to enzymatic and alkali digestion as described in Fig. 3, before further chromatographic analysis of the digestion products, *a*, α-^{32}P-labelled inhibitor: 1 and 2, alkali digest of BAP-treated inhibitor with unlabelled pA or Ap (mix of 2′ and 3′), respectively, as markers. 3, SVPD digest with unlabelled pA marker. 4, Mixture of alkali digest of BAP-treated inhibitor plus SVPD digest of untreated inhibitor. *b*, ^3H-labelled inhibitor: alkali digest of BAP-treated inhibitor. *c*, *d*, α-^{32}P-labelled inhibitor: BAP resistant core (arrowed). Thin-layer chromatography was in 1 M acetic acid on PEI cellulose[12] for *a*, *b* and *c*: for *d* it was in *n*-propanol–concentrated ammonia–water (55:10:35, v/v/v) on cellulose (Polygram Cel 300, Machery Nagel, Camlab, Cambridge, England)[13]. Optical density markers (dotted circles) were as in Fig. 3. Detection of radioactivity was by autoradiography in *a*, *c* and *d* and by fluorography[14] in *b*.

biological activity. It seems reasonable to conclude that the major radioactive component (arrow Fig. 3*a*) is indeed the biologically active inhibitor. Accordingly, a more detailed analysis of its digestion products was undertaken to obtain further information concerning its structure.

Digestion of the α-^{32}P or ^3H-labelled inhibitor with SVPD yielded 5′ AMP as the only major product (Fig. 3*a* track 2, and Fig. 4*a* track 3 for ^{32}P: data for ^3H not presented). Sequential degradation with BAP and alkali yielded $^{32}P_i$, 2′-AMP and 3′ AMP (in approximately equal amounts, Fig. 3*a* track 8 and Fig. 4*a* tracks 1 and 2) and ^3H-labelled adenosine, 2′ AMP and 3′ AMP (Fig. 4*b*). The BAP-resistant core of the molecule, however, is not simply ApApA. It migrates to a point intermediate between $(Ap)_2A$ and $(Ap)_3A$ on chromatography in a system which separates according to size (Fig. 4*d*) and migrates with neither of these markers when chromatographed on PEI cellulose with 0.75 M potassium phosphate *p*H 3.4 (Fig. 3*a*) or acetic acid (Fig. 4*c*) solvents. Moreover, even after removal of all BAP-sensitive phosphate the α-^{32}P or ^3H-labelled 'BAP core' of the inhibitor remains resistant to, for example, P1 and T2 nucleases in conditions of complete digestion of ApA or $(Ap)_2A$ included in the same reaction mix (data not presented). The possible involvement of pA residues linked 2′–5′ rather than 3′–5′ has not been tested. Overall it seems unlikely from these results that the LMW inhibitor corresponds directly to the possible 'pleiotypic activator' A(5′)pppp(5′)A (ref. 15), or to the various analogues of the 5′-terminal cap structures of messenger RNA (ref 16). These latter, for example, seem to be required at much higher concentration ($\geq 10\ \mu M$) than the LMW inhibitor to be effective in the inhibition of cell-free protein synthesis[17–20].

From our previous work it remained possible that the heat-stable LMW inhibitor might be a small phosphorylated polypeptide product of the dsRNA-dependent protein kinase present in extracts from interferon-treated cells. This is not the case. Here we have shown that although the inhibitor is resistant to a variety of nucleases it is sensitive to digestion with SVPD, BAP and alkali and can be labelled with ^3H and α-^{32}P-ATP as well as with γ-^{32}P-ATP. It apparently contains two or more AMP residues in SVPD and alkali-labile linkage. Its precise nature remains to be determined, but the results suggest that it is a 'di- or oligonucleotide' of unusual or modified structure which is effective at subnanomolar concentrations in the inhibition of protein synthesis in cell-free systems from mouse L-cells or rabbit reticulocytes.

We thank Dr Beverley Griffin for enzymes, for assistance in initiating the characterisation studies and for helpful discussion. A. G. H. was the recipient of a Wellcome Trust Fellowship.

Effects of sodium butyrate on synthesis of human chorionic gonadotrophin in trophoblastic and non-trophoblastic tumours

SOME human tumours and tumour-derived cell lines are capable of producing 'eutopic' peptide hormones and other proteins that are normally synthesised by the tissue from which the tumour originated. For example, choriocarcinoma cells, which are derived from cancer of the placental trophoblast, can synthesise human chorionic gonadotrophin (hCG) (refs 1, 2), and cultured pituitary adenomas can produce growth hormone (GH) (ref. 3). On the other hand, it is well established that a variety of malignant human tumours can produce 'ectopic' peptide hormones and other proteins which are not normally associated with the tissue of origin[4–8]. Ectopic synthesis of placental proteins, including the placental isoenzyme of alkaline phosphatase as well as the hormones hCG and human placental lactogen, may provide specific markers for neoplasm, since these proteins are not normally found in measurable amounts in the serum of men or of non-pregnant women[9]. Several human glycoprotein trophic hormones, including hCG, thyroid-stimulating hormone (TSH), luteinising hormone (LH), and follicle-stimulating hormone (FSH), are composed of two non-identical subunits, α and β (refs 10–13). These four hormones have virtually identical α subunits; in contrast each has a unique β subunit, which is responsible for biological specificity[14]. Complete hCG and free subunits are secreted by

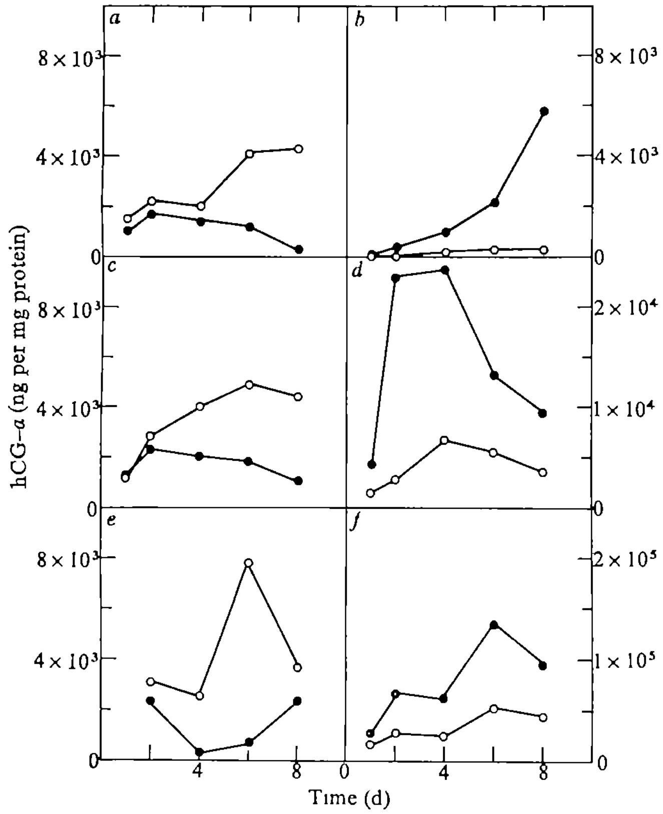

Fig. 1 Effect of sodium butyrate on hCG-α synthesis. *a*, JEG-3; *b*, HeLa CCL2; *c*, Reid; *d*, HeLa S$_3$ *e*, BeWo; *f*, ChaGo. Cultures were grown at 37 °C in 25-cm^2 flasks in 5 ml of α MEM (BeWo, ChaGo and HeLa cells) or Ham's F-12 (JEG-3 and Reid) supplemented with 10% foetal bovine serum. Media and serum were obtained from Flow Laboratories, Rockville, Maryland. Media were replaced every 2 d. HCG-α and hCG concentrations in the culture medium were measured by a specific double-antibody radioimmunoassay using hCG-α and hCG as reference standards[15]. For measurement of cellular protein content, cells were collected by removing the medium, washing the cells twice with saline, and scraping the cells off the plastic surface with a rubber policeman. The cells were collected by centrifugation and then frozen. The frozen pellet was resuspended in 0.3 ml buffered saline (0.9% NaCl in 0.01 M Tris-HCl, *p*H 7.4), and the cells were ruptured by sonication (Raytheon Magnetostrictive Oscillator, Model DF-101, Raytheon, Manchester, New Hampshire). The sonicates were centrifuged at 10,000g for 15 min. Total protein in the supernatant solutions was determined by the method of Lowry *et al*[19]. ○, Control; ●, 2 mM sodium butyrate.

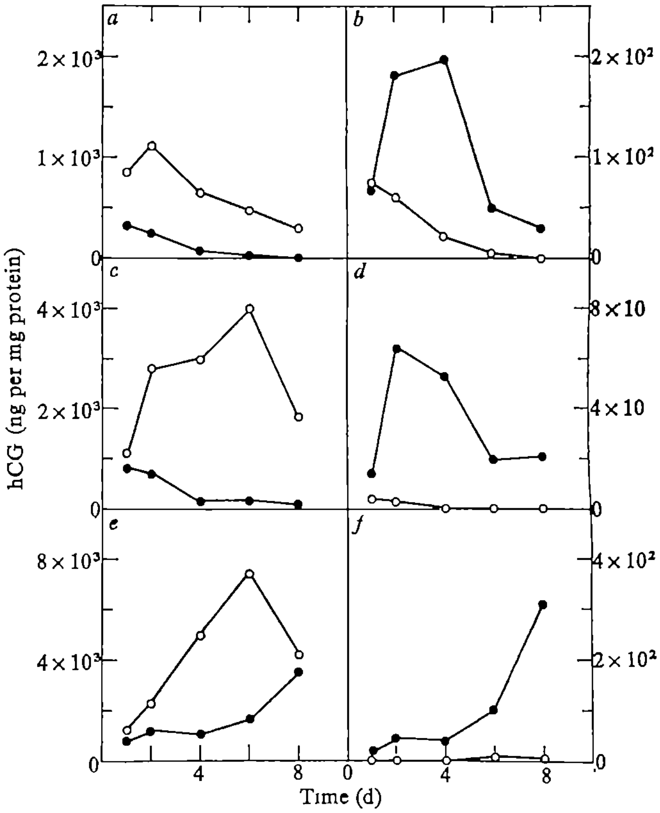

Fig. 2 Effect of sodium butyrate on hCG synthesis. *a–f* And conditions as in Fig. 1. ○, Control; ●, 2 mM sodium butyrate.

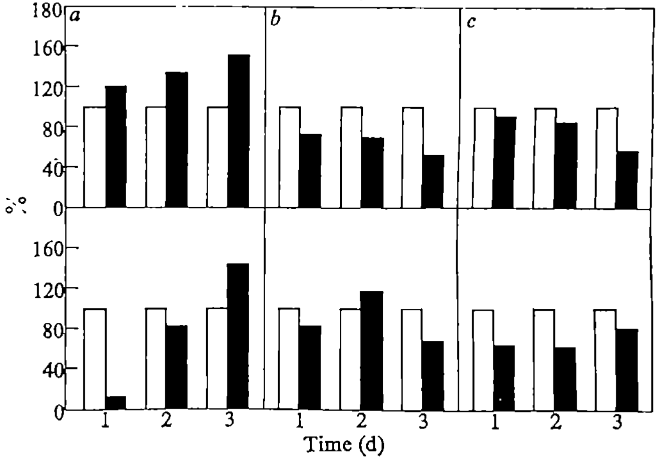
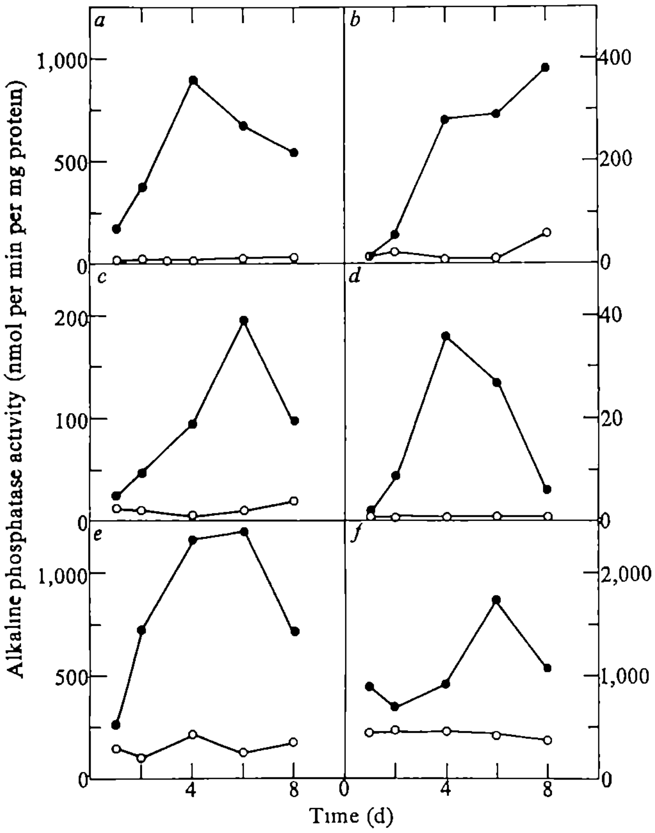
Fig. 3 Effect of sodium butyrate on the rate of synthesis of cell DNA, RNA and protein. Monolayers of JEG-3 (top row) or HeLa S$_3$ cells (bottom row) were incubated with medium containing 2 mM sodium butyrate. At indicated times, cells were labelled with (*a*) methyl-^{3}H-thymidine (5 μCi ml^{-1}), (*b*) ^{3}H-uridine (5 μCi ml^{-1}), or (*c*) ^{3}H-leucine (5 μCi ml^{-1}), for 1 h at 37 °C (radioisotopes were purchased from New England Nuclear, Boston, Massachusetts). After removal of the radioactive medium, the cultures were washed with phosphate-buffered saline, and the cells were lysed with 0.01 M Tris-HCl, *p*H 7.5, containing 0.6% SDS and 10 mM EDTA. Macromolecules in samples of the lysates were precipitated with an equal volume of 10% cold TCA. The precipitates were collected on GFC glass fibre filter disk (Reeve Angel Laboratory, Clifton, New Jersey) and washed extensively with 5% TCA. The filters were dried and the radioactivities were measured. Data are expressed as percentages of control values. Open bars, control; solid bars, sodium butyrate.



normal and neoplastic placenta[1,2,14] and by many non-trophoblastic tumours[15,16]. Since hCG is a eutopic hormone for trophoblastic tumours, but an ectopic hormone for non-trophoblastic tumours, it occured to us that its synthesis by the two types of tumours might be regulated differently. We therefore compared the synthesis of hCG and hCG-α by three choriocarcinoma cell lines—BeWo (ref. 1), JEG-3 (ref. 2) and Reid (P. O. Kohler, unpublished observations)—with the synthesis by two non-trophoblastic tumour-derived cell lines—ChaGo and HeLa. (ChaGo was derived from an hCG-producing pulmonary carcinoma[16], and HeLa from a carcinoma of the cervix[17].) We also tested the effects of sodium butyrate on the synthesis, since this compound had been shown to induce hCG-α and hCG synthesis in certain HeLa cells[18]. We found that in the absence of inducer, all of the cell lines can produce hCG-α—the trophoblastic tumour cells at roughly comparable rate, but the non-trophoblastic tumour cells at widely different rates (Fig. 1).

The basal production of complete hCG by the non-trophoblastic tumour cells is only marginal compared with its synthesis by the choriocarcinoma cells (Fig. 2). Sodium butyrate has strikingly different effects on the two classes of tumour cells: it induces synthesis of hCG-α and hCG in the non-trophoblastic tumour cells, but represses it in the trophoblastic tumour cells (Figs 1 and 2). Because of its differential effects on synthesis, we thought it possible that sodium butyrate might be more toxic for the choriocarcinoma cells. This is unlikely, however, for two reasons. Sodium butyrate inhibited the incorporation of uridine and leucine at roughly the same degree in JEG-3 and HeLa S$_3$ cells (Fig. 3). Although sodium butyrate slightly enhanced the incorporation of thymidine in JEG-3 cells but transiently inhibited the incorporation in HeLa S$_3$ cells, the long term effects seemed to be the same for both types of tumour cells (Fig. 3). The placental isoenzyme of alkaline phosphatase was induced by this compound in all cell lines examined (Fig. 4). Furthermore, since intracellular and extracellular hCG-α and hCG are affected to the same extent by sodium butyrate (data not given), the observed reduction of these proteins in choriocarcinoma cells and induction in non-trophoblastic tumour cells are not due to its effects on hormone secretion.

Fig. 4 Effect of sodium butyrate on alkaline phosphate activity. *a–f* and conditions as in Fig. 1. Alkaline phosphatase activity in the sonicates was measured by release of *p*-nitrophenol from *p*-nitrophenyl phosphate at *p*H 10.7 and 37 °C (ref. 20). ○, Control; ●, 2 mM sodium butyrate.



Our data indicate that the regulation of hCG and hCG-α production differs in placental and non-placental tumours. Detailed analysis of the molecular mechanisms underlying the biosynthesis of this peptide hormone by these cell lines may yield insight into the essential nature of ectopic protein production.

We thank Dr K. Catt, Dr G. Hodgen and Dr H. Chen for antisera used in the radioimmunoassays. We also thank Drs S. W. Rosen and A. S. Rabson for gifts of ChaGocells.

Potent prolactin and growth hormone releasing activity of more analogues of Met-enkephalin

MORPHINE stimulates prolactin and growth hormone secretion[1,2], so the identification of brain peptides with opiate-like activity (methionine-enkephalin and leucine-enkephalin)[3] raised the possibility that these peptides, beside their role as modulators of pain[4], could also be involved in the control of neuroendocrine functions. We did in fact find that Met-enkephalin administered intraventricularly led to a stimulation of prolactin and growth hormone release[5–7]. β-Endorphin (β-LPH$_{61-91}$) was, however, found to be 500 to 2,000 times more potent than Met-enkephalin (β-LPH$_{61-65}$) in stimulating the release of the pituitary hormones. Since both peptides show similar affinity for the opiate receptor when binding studies are performed at 0 °C in conditions of minimal enzymatic degradation[8,9], the markedly different biological activities of the two peptides after intracerebral injection are likely to be due to a more rapid inactivation of Met-enkephalin. We show here that the two analogues resistant to enzymatic degradation, [D-Ala^2]Met-enkephalin and [D-Ala^2]Met-enkephalinamide can stimulate prolactin and growth hormone release after intraventricular injection at a level of potency which is 500 to 5,000 times higher than that of the natural Met-enkephalin molecule.

Since both plasma[10,11] and brain tissue[11] contain high levels of enzymatic activity hydrolysing the Tyr^1–Gly^2 bond as the initial step of inactivation of Met-enkephalin, we first tested

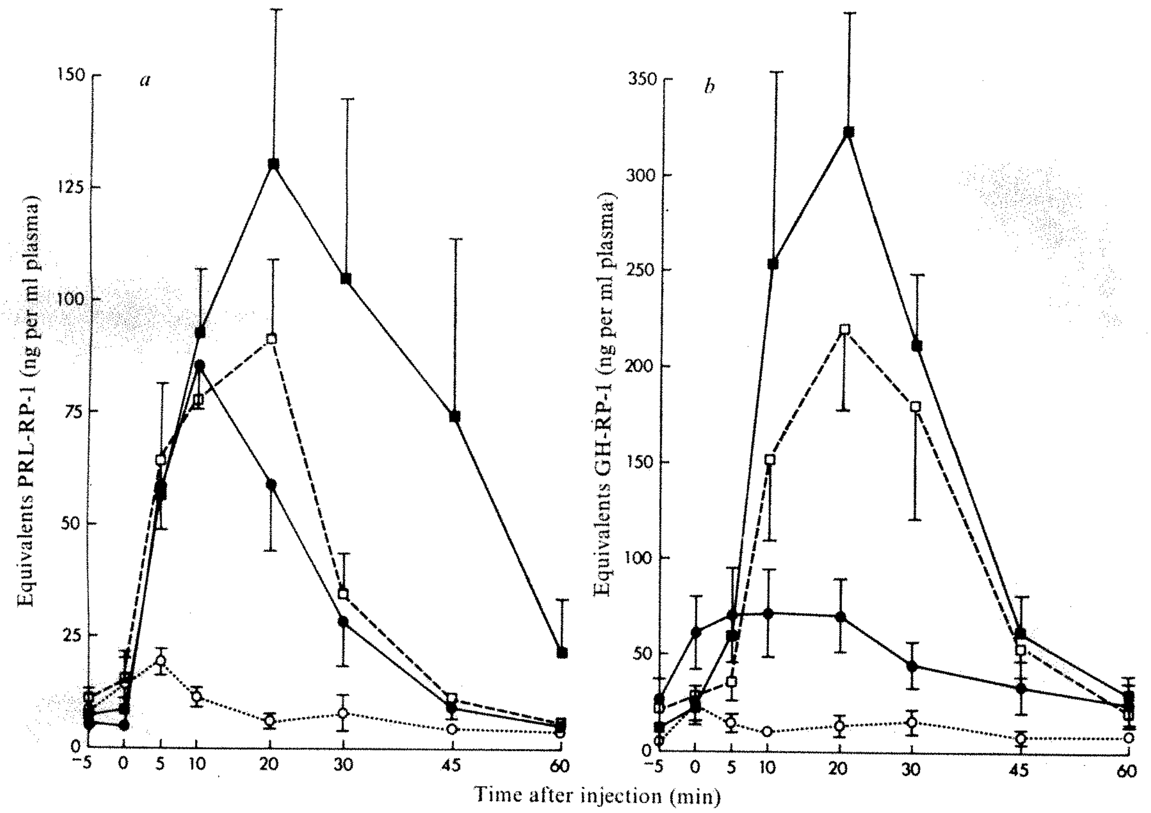

Fig. 1 Effect of increasing doses of Tyr–D–Ala–Gly–Phe–Met ([D-Ala^2]Met-enkephalin) on plasma prolactin (*a*) and growth hormone (*b*) levels in the rat. To minimise stress-induced inhibition of growth hormone (GH) and stimulation of prolactin (PRL) release, adult male Sprague–Dawley rats (225–250 g) were handled twice a day for 7–10 d before insertion of a catheter into the right superior vena cava under Surital (50 mg per kg body weight, i.p.) anaesthesia. The animals were then implanted stereotaxically with a stainless steel cannula (25 gauge) in the left lateral ventricle. Two days later, animals were injected through the intrajugular catheter with 0.5 ml of sheep anti-somatostatin serum 5 min before injection of the peptides to be tested which were injected in a volume of 40 µl of 0.9% NaCl over a 3-min period in freely-moving animals. Blood samples of 0.7 ml were then withdrawn at the indicated time intervals for measurement of plasma GH and PRL by double-antibody radioimmunoassays using materials provided by NIAMDD. Data are expressed as mean ± s.e.m. of triplicate determinations. Correct placement of the intracerebral cannulae was confirmed by injection of 10 µl of methylene blue at the time animals were killed. The peptides used were synthesised by solid-phase methods and purified as before[12]. ○, Control; ●, □, ■; [D-Ala^2]Met-enkephalin at 50, 150 and 300 µg respectively.

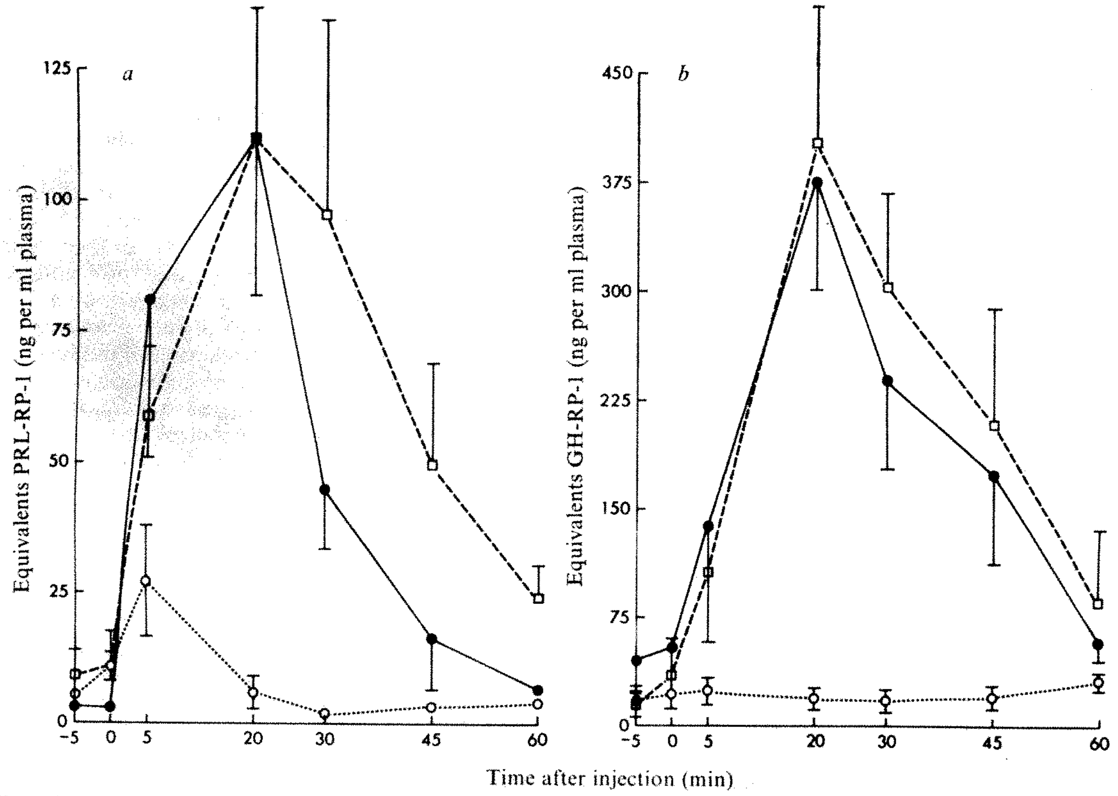

Fig. 2 Effect of intraventricular injection of 62 or 200 µg of [D-Ala^2]Met-enkephalinamide on plasma prolactin (*a*) and growth hormone (*b*) levels in the rat. The experiment was performed in conscious freely-moving adult male animals bearing chronic intraventricular and intrajugular cannulae as for Fig. 1. ○, Control; ●, 62.5 µg and □, 200 µg [D-Ala^2]Met-enkephalinamide.

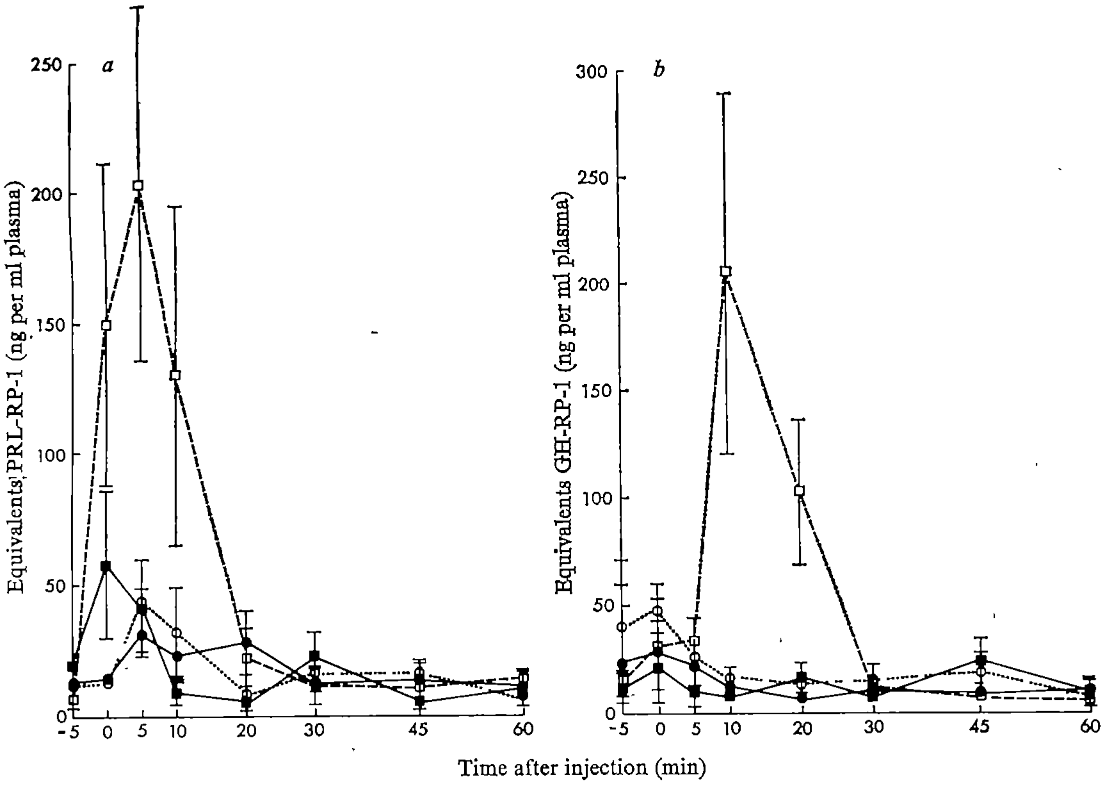

Fig. 3 Effect of intraventricular injection of 400 μg of *N*-acetyl [D-Ala^2]Met-enkephalin (●), Met-enkephalin-ethylamide (□) or [D-Tyr^1]Met-enkephalin (■) on plasma prolactin (*a*) and growth hormone (*b*) levels in the rat. ○, Control. The experiment was performed in conscious freely-moving adult male animals bearing chronic intraventricular and intrajugular cannulae as described in Fig. 1.

the growth hormone and prolactin releasing activity of analogues of Met-enkephalin that seemed to be resistant to degradation, retained their activity for the opiate receptor[8,9] and were found to be potent agonists in the vas deferens assay[12].

The minimal effective dose of Met-enkephalin on growth hormone and prolactin release after intraventricular injection in the rat is approximately 400 μg (refs 5–7), but it can be seen in Fig. 1 that [D-Ala^2]Met-enkephalin has a maximal stimulatory effect on prolactin and growth hormone release at the doses of 50 and 150 μg, respectively. As observed previously with Met-enkephalin and β-endorphin[5–7,20] the stimulatory effect of [D-Ala^2]Met-enkephalin is exerted at a lower dose and earlier after its injection on prolactin than growth hormone release. In fact, while an important stimulatory effect of the Met-enkephalin analogue on plasma prolactin levels was seen 5 min after its injection, the effect on plasma growth hormone levels was detected 5 min later.

Substitution of D amino acids in position 6 of the decapeptide luteinising hormone-releasing hormone (LHRH) leads to peptides with much greater potency and duration of action[13,14] while replacement of the tryptophan residue at position 8 in somatostatin by its D-isomer enhances the growth hormone-release inhibiting activity of the molecule approximately eightfold[15]. Our data show that substitution of the glycine residue of Met-enkephalin by D-alanine leads to a dramatic increase of the growth hormone and prolactin releasing potency of the peptide. Figure 1 indicates that [D-Ala^2]Met-enkephalin given by intraventricular injection is 1,000 to 2,000 times more potent than Met-enkephalin itself.

Met-enkephalinamide has been reported to be slightly more effective than Met-enkephalin in an opiate receptor assay[9,16], so it is interesting to note than [D-Ala^2]Met-enkephalinamide (Fig. 2) is about five times more potent than [D-Ala^2]Met-enkephalin as stimulator of growth hormone and prolactin release. In fact, while maximal stimulation of prolactin and growth hormone release is obtained with [D-Ala^2]Met-enkephalin at the 300-μg dose, a similar effect was obtained with 62.5 μg of [D-Ala^2]Met-enkephalinamide, a peptide at least 5,000 times more potent than Met-enkephalin in this assay.

In agreement with our receptor binding studies[9,12] and vas deferens bioassays[12], [D-Tyr^1]Met-enkephalin and *N*-acetyl Met-enkephalin did not show any growth hormone or prolactin releasing activity at the 400 μg dose, thus indicating the importance of the L-tyrosine residue for biological activity of the molecule. Substitution of the C-terminal glycine-amide residue in the LHRH molecule by ethylamide led to an analogue 10 to 15 times more potent than the natural hormone[17]. It is interesting to note that addition of the ethylamide group at the COOH-terminus of Met-enkephalin markedly increased its growth hormone and prolactin releasing activities (Fig. 3).

Our data show that two Met-enkephalin analogues studied have an activity comparable with that of β-endorphin itself as stimulators of growth hormone and prolactin release after intraventricular injection. These analogues should be useful for study of the physiological role of endogenous opiate peptides, not only as analgesics[18] and behavioural modulators[19] but also in the control of neuroendocrine functions. These data and previous work[5–7,20] in fact suggest that endogenous opiate-like peptides are involved in the control of growth hormone and prolactin secretion. The model described here could also be useful for precise assessment of the biological activity of endogenous and synthetic opiate-like substances.

A synthetic enkephalin analogue with prolonged parenteral and oral analgesic activity

METHIONINE and leucine enkephalin, the morphinomimetic pentapeptides from mammalian brain[1-3] produce a weak and short-lived analgesia following intracerebroventricular (i.c.v) or intravenous (i.v.) administration to mice[4] and rats[5]. β-endorphin[6,7], another morphinomimetic fragment of β-lipotropin but with 31 amino acid residues, shares its amino-terminal sequence with met-enkephalin. In addition to showing marked and long-lived analgesic activity following i.c.v. and i.v. administration[8-10], the pronounced effects of β-endorphin have led to the suggestion that it may be implicated in the aetiology of mental illness[11-13]. We report here a number of the pharmacological properties of five synthetic pentapeptides structurally related to met-enkephalin, two of which exhibit significant analgesic activity after oral administration and which are more potent analgesics administered parenterally than β-endorphin.

The enkephalin analogues were prepared by fragment condensation methods. Analgesia was estimated in the mouse (tail flick[14] and hot plate[15,16] procedures), the rat (paw pressure test based on the technique described by Randall and Selitto[17]) and the rhesus monkey (shock titration test[18-20]). The affinity for opiate receptors was assessed by the inhibition of ^{3}H-naloxone binding to rat brain membranes using a method described previously[4].

Fig. 1 Structural formula of 33–824

In the tail flick test (Table 1), met-enkephalin exhibited short-lasting analgesia following i.c.v. and i.v. administration[4]. A gradual increase of analgesic potency and duration after i.c.v. administration resulted from the alteration of the carboxyl group to the carbinol analogue (Met^5-ol), the substitution of the glycine residue in position 2 by D-alanine (D-Ala^2,-Met^5), and the combination of these two modifications (D-Ala^2,Met^5-ol). The latter derivative showed subcutaneous as well as prolonged i.c.v. and i.v. analgesic activity. In contrast, the corresponding (D-Ala^2,Met^5) enkephalin amide[11] was only active following i.c.v. administration. Oxidation to the sulphoxide (D-Ala^{2}Met(O)^5-ol) and *N*-methylation of the phenylalanine residue gave compound FK 33–824 (referred to throughout as 33-824), (D-Ala^2,MePhe^4, Met(O)^5-ol)-enkephalin (Fig. 1), which produced definite analgesic activity even after oral administration. 33-824 was, on a molar basis, not only about 30,000 and 1,000 times more potent than met-enkephalin and morphine respectively after i.c.v. administration, but also 23 times as active as β-endorphin.

In binding studies using ^{3}H-naloxone[22] and rat brain membranes (Table 1) met-enkephalin and its Met^5-ol derivative had a greater affinity for the opiate receptor in the presence of the enzyme inhibitor[23] bacitracin than in its absence, indicating that even in this *in vitro* system, both compounds are subjected to inactivation. For all the other compounds including morphine, the dose–response curves for opiate-receptor binding were not affected or were shifted only slightly to the right, suggesting that these compounds are sufficiently stable in the *in vitro* conditions used. In agreement with the *in vivo* results,

Table 1 Analgesic activity in the mouse and inhibition of ^{3}H-naloxone binding to rat brain membranes

*At 2 min; †at 15 min; ‡at 30 min.

The ED$_{50}$ value[33] for the analgesic activity in the tail-flick test is defined as the dose that prolonged the reaction time (in s) by more than 75% in half the animals. Ten animals were used per dose. All doses refer to the free base. The IC$_{50}$ is the concentration of substance required to inhibit by 50% the specific binding of ^{3}H-naloxone (1 nM) to pre-incubated (30 min at 37 °C) membranes of rat brain minus cerebellum in 0.05 M Tris buffer (*p*H 7.4 at 25 °C). Five concentrations of each compound were incubated in triplicate at 25 °C for 40 min in the presence of 100 mM NaCl (refs 4, 25). Filtrations were performed at ı25 °C. Specific binding is the difference between ^{3}H-naloxone binding in the absence and presence of 1 μM levallorphan. Values are the mean of at least three determinations with s.e.m. of less than 15%.

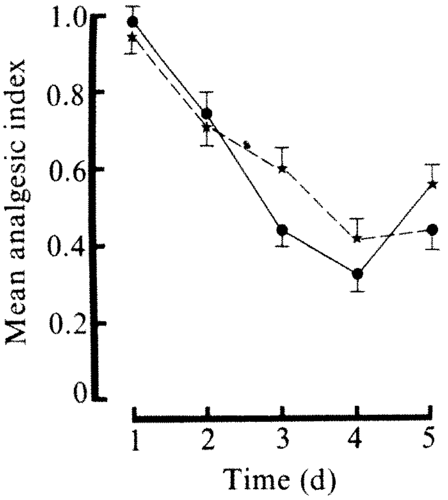

Fig. 2 Mean analgesic index (± s.e.) recorded in the paw pressure test in the rat[28] following s.c. administration of morphine (7.5 mg kg^{-1}, ●) and 33–824 (3.2 mg kg^{-1}, ★) twice daily for 4 d. On day 5, 33–824 (3.2 mg kg^{-1} s.c.) was given to the morphine-pretreated rats and morphine (7.5 mg kg^{-1} s.c.) to the 33–824-pretreated animals. Twenty rats were in each group. The reaction thresholds were recorded immediately before and 30 min after each injection (0815 h and 1545 h).

33–824 displayed the highest affinity for the opiate receptor. The data in Table 1 indicate that in the absence of bacitracin an approximately 30-fold increase in affinity was observed between the least (met-enkephalin) and the most (33-824) potent compound in this series. This increase is much smaller than the dramatic, graded increase observed *in vivo*. The 'sodium response ratio' for 33-824, calculated from the ID$_{50}$ values obtained in the presence and the absence (data not shown) of NaCl (ref. 24), was 8.2, thereby placing it in the same range as the partial morphine agonist pentazocine which had a ratio of 7.1 (ref. 4). Since there is *in vivo* no evidence to suggest that 33-824 possesses morphine antagonistic properties, the value of the 'sodium response ratio' as a predictor[24] of the degree of morphine-like activity of opioid peptides remains uncertain[25].

In a more detailed comparison of the analgesic properties of 33-824 and morphine (Table 2), 33-824 was about twice as potent subcutaneously in the mouse and rat. Thirty minutes after oral administration, however, 33-824 was 5 (tail flick) and 3.5 times (hot plate) less active than morphine. The similarity of the ED$_{50}$s obtained with 33-824 in the inflamed and non-inflamed paws in the paw pressure test confirm the central nature of its analgesic effect. Aspirin, with a predominantly peripheral analgesic effect[26], only affects the threshold in the inflamed paw. In the rhesus monkey, 33-824 was parenterally about 2–3 times less potent than morphine, depending on the route of administration. Following rectal administration, however, 33-824 was active whereas no analgesic effect was observed with morphine. The degree and duration of analgesia with 33-824 was dose dependent in all species investigated. In the mouse (tail flick) the ED$_{50}$s after i.v. administration at 0.5 and 2 h were 0.4 and 0.8 mg kg^{-1} respectively. Orally, in the same test, the ED$_{50}$ increased between 2 and 3 h after administration from 102 to 114 mg kg^{-1}. In the rhesus monkey the duration of action following i.v. administration of the minimal effective dose was at least 5 h.

The parallel displacement to the right of the analgesic dose–response curves of 33-824 and morphine in the tail-flick test in a manner similar to that obtained with methionine enkephalin[4] following pretreatment with naloxone (0.56 mg kg^{-1} i.v.), provide evidence for the morphine-like qualities of 33-824. This was confirmed by the ability of 33-824 to produce mydriasis and a Straub tail response in the mouse, that were abolished by naloxone administration. Repeated administration of 33-824 to rats twice daily for four consecutive days[27] resulted in the development of tolerance to its analgesic effect in the paw pressure test and cross-tolerance with the analgesic effect of morphine given on day 5 (Fig. 2). In rats similarly pretreated with morphine, 33-824 exhibited a markedly reduced analgesic effect (Fig. 2).

In the single dose suppression test[28] in morphine-dependent rhesus monkeys (3.2 or 5.6 mg kg^{-1} i.v. 6 times daily for a minimum of 4 weeks), 33-824 (1.8–5.6 mg kg^{-1} i.v.) abolished the morphine withdrawal syndrome. Substitution of morphine injections in morphine-dependent, non-withdrawn rhesus monkeys by 33-824 (1.8 mg kg^{-1} i.v. at 4 h intervals for 24 h) prevented the appearance of the morphine withdrawal syndrome. In a self-administration study in three male, drug-naive rhesus monkeys[29], 33-824 (0.01 and 0.032 mg kg^{-1} i.v. per injection), was not self-administered in spite of continual access to the drug for a total of 4 weeks. When the concentration was increased to 0.1 mg kg^{-1} i.v. per injection, all three animals started to exhibit self-administration behaviour which increased gradually over a period of 5 weeks, until the mean daily amount self administered was about 13 mg kg^{-1} i.v. (Table 3). Naloxone (i.v.) produced a marked withdrawal syndrome resembling that observed following opiate withdrawal and saline substitution for 33-824 injections resulted in all three monkeys in the occurrence of a marked opiate-like withdrawal syndrome lasting 2–3 d and accompanied during the first 48 h by an increase in lever-pressing activity (Table 3).

33-824 (10 mg kg^{-1} i.p.) was devoid of morphine-antagonistic properties in the mouse as, in contrast to naloxone (0.56 mg kg^{-1} i.p.), it did not produce jumping behaviour in morphine-dependent[30] mice. Thus, 33-824 may be regarded at this stage as being a pure morphinomimetic drug without any antagonistic properties.

33-824 (10 μg per rabbit) administered into the 4th ventricle produced a marked catatonia characterised by muscular rigidity and immobility lasting at least 2 h and which had the same outward appearance as that exhibited by β-endorphin in rats[11,12]. Morphine (1 mg per rabbit in 0.1 ml) injected directly into the 4th ventricle caused marked respiratory depression

Table 2 Analgesic activity of 33–824 and morphine

*At 60 min; † at 30 min.

ED$_{50}$ values[33] for the analgesic activity in the tail-flick, hot plate, and paw pressure tests are defined as the doses that prolonged either the reaction time (in s) or the reaction pressure (mmHg) by more than 75% in half of the animals. Ten animals were used per dose. The minimal effective dose in the shock titration test is the dose that increased the mean tolerated threshold by more than 45% in three of six post-treatment sessions. All doses refer to the free base.

and death but no catatonia, thereby confirming the results obtained in a similar study in the rat.[11] 33-824 (32 mg kg^{-1} s.c.) also caused catatonia in the rat. As in the case of β-endorphin[9,11], the catatonic effects of 33-824 were abolished by naloxone. β-Endorphin also resembles 33-824 in that it produces tolerance to its own analgesic effect[31], exhibits cross tolerance with morphine and causes physical dependence[32].

The major finding of the present studies is that by appropriate modification of enkephalin it is possible to construct a synthetic pentapeptide possessing many of the biological properties exhibited by the untriacontapeptide β-endorphin. The outstanding characteristic of 33-824 is that its long-lasting analgesic effect after systemic administration is superior to that of β-endorphin. Furthermore, 33-824 is one of the rare examples of a peptide showing pronounced biological activity after enteral administration. The ready availability and the stability of 33-824 should make it valuable for further studies of the mode of action of opioid peptides.

We thank Dr J. Rivier, Salk Institute for the gift of β-endorphin.

Opiate analgesics inhibit substance P release from rat trigeminal nucleus

THE undecapeptide substance P (SP) may act as a transmitter released from the terminals of primary sensory nerves in the spinal cord[1–2]. SP has been shown to be highly concentrated in the terminals of small diameter fibres in the substantia gelatinosa of the dorsal horn in mammalian spinal cord, and these terminals disappear after dorsal root section[3–6]. Sensory nuclei of some of the cranial nerves, such as the spinal trigeminal nucleus, also contain a high density of SP nerve terminals[6–7]. SP is released by a calcium-dependent mechanism from the isolated rat spinal cord during electrical stimulation of the dorsal roots[8]. The peptide is also a powerful excitant of neurones in the spinal cord[2], and seems to excite selectively those cells in dorsal horn that respond to noxious stimuli[9–10]. SP may, therefore, represent the excitatory transmitter, or one of the transmitters, released from primary fibres involved in the transmission of pain. We have examined the stimulus-evoked release of SP from rat spinal trigeminal nucleus slices *in vitro* to explore the factors which may control its release from primary sensory terminals. We report here that opiate analgesics are able to suppress the stimulus-evoked release of SP. These findings may represent a mechanism for the direct spinal analgesic actions of opiates.

In the mammalian spinal cord and cranial nerve nuclei, there is a striking similarity between the anatomical distributions of opiate receptor binding sites and the endogenous opioid peptide, enkephalin[11–12]. The results of SP assays on microdissected areas of rat brain stem and spinal cord show that SP is similarly distributed (Fig. 1).

For release studies we used the techniques previously developed for studying the calcium-dependent release of SP from slices of rat hypothalamus or substantia nigra *in vitro*[13,14]. Spinal trigeminal nerve nuclei were dissected from fresh chilled 0.8 mm thick coronal sections of rat brain stem, using a stereomicroscope. The pooled tissue samples from several rats (approximately 10 mg wet weight from one rat brain) were sliced at 0.2-mm intervals in two directions with a McIlwain tissue chopper, and approximately 20 mg of tissue was transferred to each chamber of a four-channel superfusion apparatus[13]. After washing (0.375 ml min^{-1}) for 5 min with Krebs bicarbonate solution at 37 °C containing 0.5% bovine serum albumin and the peptidase inhibitor bacitracin (20 μM), superfusate samples were collected at 1-min intervals and SP-like immunoreactivity measured as described previously[13]. The spontaneous efflux of SP was equivalent to 0.2–0.4% of the total tissue content/min. As in previous experiments with slices of hypothalamus or substantia nigra[13,14], brief exposure to a medium containing 47 mM potassium chloride (K$^+$)

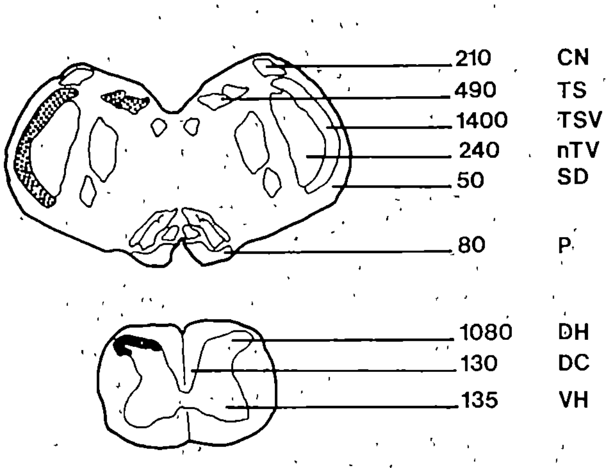

Fig. 1 Comparative distribution of opiate receptor binding and SP in rat brain stem and spinal cord. Diagrammatic representation of coronal sections of (a) rat medulla, 2 mm caudal to the obex; and (b) rat cervical spinal cord. Opiate receptor binding data are adapted from Atweh and Kuhar[11]. The left-hand side of each section shows areas with dense (solid black) or moderate (stippled) opiate receptor binding. The right-hand side of each section gives the SP concentrations expressed as pmol per g wet weight in areas obtained by microdissection. Each value is the mean ± s.e.m. of at least four animals (measured by radioimmunoassay as described previously[4]). CN, Nucleus cuneatus; TS, nucleus tractus solitarius; TSV, tractus spinalis nervi trigemini (substantia gelatinosa); nTV, nucleus tractus spinalis nervi trigemini; SD, tractus spino-cerebellaris dorsalis; P, pyramis; DH, dorsal horn; DC, dorsal column; VH, ventral horn.

elicited a marked increase in the release of immunoreactive SP, with efflux returning to basal levels soon after removal of K+ (Fig. 2*a*). Addition of morphine to the superfusing medium for 7 min before K+ application produced a concentration-dependent inhibition of the evoked release of SP, without affecting the spontaneous efflux (Fig. 2*b*). At a morphine concentration of 10 μM, the K+-evoked release of SP was almost completely supressed. Continuous superfusion with naloxone (1 μM) commencing 2 min before addition of 10 μm morphine caused an almost complete reversal of the effect of morphine on SP release (Fig. 2*c*). Superfusion with naloxone alone (1 μM) failed to affect the spontaneous efflux of SP or the K+-evoked release.

The opiate effect was stereospecific in that levorphanol (5 μM) produced an almost complete inhibition of the K+-evoked release of SP, whereas the inactive enantiomer dextrorphan did not significantly inhibit SP release at a tenfold higher concentration (50 μM) (Fig. 2*d*). Another opiate analgesic, normorphine (5 μM), similarly suppressed the K+-evoked release of SP, and this effect could be partially reversed by addition of the potent opiate antagonist diprenorphine (1 μM) 2 min before addition of normorphine (Fig. 2*e*).

A number of naturally occurring peptides with morphine-like properties, the endorphins, have been described[15-16], which vary considerably in metabolic stability and analgesic potency. In the present studies we tested the Met-enkephalin analogue [D-Ala]^2-Met-enkephalin-amide (Peninsula Laboratories), which is reported to be metabolically stable and to possess high analgesic potency[17]. A low concentration of this peptide (3 μM) almost completely suppressed the K+-evoked release of SP, and this inhibitory effect was reversed by naloxone (1 μM) (Fig. 2*f*). In other experiments (results not shown), another opioid peptide with similar metabolic stability and high analgesic potency[18], β-endorphin (Peninsula Laboratories), was found to produce 43.3 ± 8.1% (mean ± s.e.m., $n = 4$) inhibition of K+-evoked SP release at an even lower concentration (0.5 μM).

We also examined the effects of morphine and β-endorphin on the release of SP from slices of rat substantia nigra, a region of rat brain that contains a concentration of SP comparable with that found in the substantia gelatinosa of the spinal nucleus of the trigeminal nerve[4]. No significant inhibition of the spontaneous or K+-evoked release of SP from nigral tissue was observed with morphine or β-endorphin. In control experiments, exposure to K+ evoked a total increase in SP release equivalent

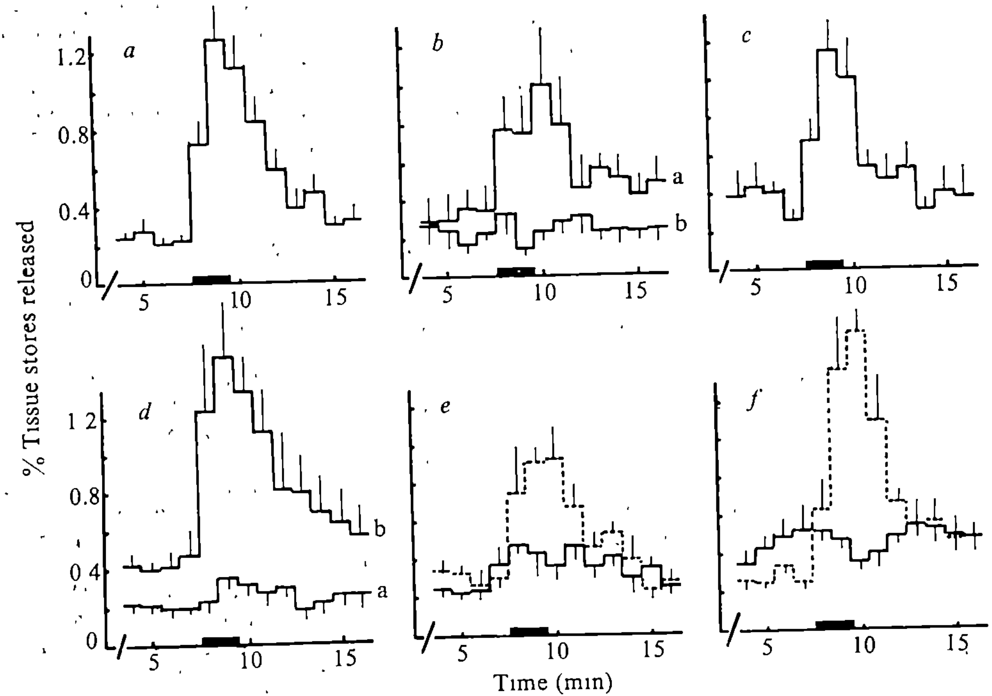

Fig. 2 Effect of opiates on the release of SP from superfused slices of spinal trigeminal nucleus from rat brain. Efflux of SP is expressed as the percentage of tissue content released per min. The spontaneous efflux of SP was approximately 30 fmol per fraction and the lower limit of sensitivity of the radioimmunoassay procedure was approximately 8 fmol. In *a–f*, each point is the mean ± s.e.m. of at least four experiments. Tissue slices were exposed to KCl-enriched Krebs solution (47 mM) for a 2-min period (indicated by horizontal black bar). *a*, Control (K+-evoked release of SP from superfused slices of spinal trigeminal nucleus); *b*, inhibition of K+-evoked release of SP by morphine (upper: 5×10^{-6} M; lower: 10^{-5} M); *c*, naloxone (10^{-6} M) reversal of morphine-induced (10^{-5} M) inhibition of K+-evoked SP release; *d*, effect of levorphanol (5×10^{-6} M : a) and dextrorphan (5×10^{-5} M : b) on K+-evoked SP release; *e*, inhibition of K+-evoked SP release by normorphine (continuous line; 5×10^{-6} M) and reversal by diprenorphine (dotted line; 10^{-6} M); *f*, inhibition of K+-evoked SP release by [D-Ala^2]-Met-enkephalin amide (3×10^{-6} M) (continuous line) and reversal by naloxone (10^{-6} M) (broken line).

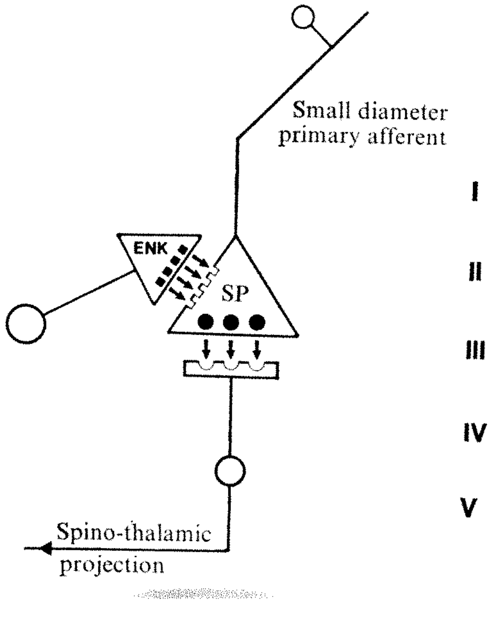
to 2.57 ± 0.26% (mean ± s.e.m.) of total tissue stores ($n = 6$). In slices exposed to 10 μM morphine, K^+-evoked release was 2.67 ± 0.29% ($n = 4$) and in two experiments with 0.5 μM β-endorphin the K^+-evoked release was 2.54 – 2.79%. Thus, opiates do not inhibit SP release from all SP-containing regions of CNS.

We believe that the present results can most easily be explained by postulating that some opiate receptors are located on primary afferent nerve terminals containing SP in the substantia gelatinosa. This would be consistent with previous work which has shown that opiates can act presynaptically to inhibit neurotransmitter release from a variety of other neurones (see, for example, ref. 19), and with the known distribution of enkephalins and opiate receptors in brain stem and spinal cord. Thus, after dorsal rhizotomy there is no change in the enkephalin content of the substantia gelatinosa area[20] but there is a significant decrease in the number of opiate receptor binding sites[21], suggesting that some of these receptors may be located on the presynaptic terminals of primary afferent neurones. Furthermore, recent immunohistochemical findings suggest that enkephalin-containing local interneurones are abundant in the substantia gelatinosa area of spinal cord and in the spinal trigeminal nerve nucleus[12,20], which represents a rostral extension of the dorsal horn, involved in the transmission of nociceptive and other information from the facial area.

The cellular mechanism by which opiates and a variety of other agents inhibit the release of transmitters from presynaptic nerve terminals remains obscure[22]. In most cases, as in the present results, control is exerted on the stimulus-evoked release of transmitter rather than on basal efflux, suggesting some interaction with the stimulus–secretion coupling mechanism, for example blockage of calcium influx[22].

A possible neuronal basis for the opiate-mediated presynaptic inhibition of primary afferent terminals and the role of enkephalins at the level of the brain stem and spinal cord is shown schematically in Fig. 3. A mechanism of this nature could account for the selective blockade by opiates of the transmission of nociceptive information in the dorsal horn[23–25], and their direct spinal analgesic actions[26]. This model could also represent the morphological substrate of the gating process proposed by Melzack and Wall[27] for the modulation of the transmission of nociceptive information within the substantia gelatinosa.

Fig. 3 Schematic representation of a possible mechanism for opiate-induced suppression of SP release. SP is shown localised within the terminal of a small diameter afferent fibre which forms an excitatory axodendritic synapse with the process of a spinal cord neurone originating in lamina IV or V and projecting rostrally. A local enkephalin-containing inhibitory interneutrone (ENK), confined to laminae II and III forms a presynaptic contact on the terminal of the primary afferent. Opiate receptor sites are depicted presynaptically on the primary afferent terminal. Numbers on the right refer to the laminae of Rexed.



T. M. J. is a MRC Scholar. SP was kindly donated by Dr R. Hirschmann, Merck, Sharp & Dohme and by Dr R. O. Studer, Hoffman-La Roche. We thank Drs J. S. Kelly and R. Dingledine for discussions.

Alterations in dopamine receptor sensitivity by chronic ethanol treatment

THE hypothermic effect of an acute dose of ethanol in animals is well established[1, 2], and the development of functional tolerance to ethanol can be monitored by measuring decreased responsiveness to the hypothermia produced by ethanol[3]. Although the central neuronal systems mediating the ethanol-induced hypothermia are at present unknown, it has been found that hypothermia caused by apomorphine and piribedil in mice and rats[4, 5] is mediated by the action of these drugs on the central dopamine receptors. Since single doses of ethanol can increase the synthesis[6, 7] and/or release[8] of dopamine in brain, the possibility exists that ethanol-induced hypothermia in rodents may be in part related to activation of dopaminergic systems. If this is the case, an altered sensitivity of dopamine receptors during chronic treatment with ethanol may be responsible for the resultant decreased sensitivity to the effects of ethanol which accompanies the development of tolerance. This paper presents evidence consistent with that possibility.

Male C57B1/6 mice were fed a liquid diet containing 7% v/v ethanol or an equicaloric amount of sucrose (controls) for 7 d (ref. 3). At the conclusion of the drinking period, all mice were offered only the sucrose-containing liquid diet (withdrawal). Using this regimen, we have previously shown that tolerance to the hypothermic and behavioural effects of ethanol is clearly evident after the 7 d of drinking and continues for up to 5 d after withdrawal[3]. In contrast, withdrawal symptoms are no longer evident at 24 h after withdrawal[3]. In the present study, tolerance to the hypothermic and hypnotic effects of ethanol was determined as previously described[3] at 24 h and at 3 and 7 d after withdrawal. At these same times, the hypothermic response to intraperitoneal (i.p.) administration of a dopamine agonist, piribedil (1-(2-pyrimidyl-4-piperonyl-piperazine))[9] was assessed. To further monitor dopaminergic

Table 1 Change in body temperature of C57Bl/6 mice after drug treatment*

Drug treatment (per kg bodyweight)	Ethanol-tolerant	Control	P†
Ethanol, 3 g	1.5±0.5 (6)	3.5±0.4 (6)	<0.01
Piribedil 20 mg	1.2±0.4 (5)	2.2±0.3 (4)	<0.1
40 mg	2.0±0.1 (6)	2.9±0.1 (6)	<0.001
60 mg	2.7±0.1 (6)	3.4±0.1 (6)	<0.001
Clonidine 0.5 mg	3.9±0.4 (4)	3.4±0.5 (4)	NS

Body temperature (°C) was monitored at 15-min intervals for 30 min before i.p. injection of the drug, and at 15-min intervals for 2 h after the drug treatment. The values recorded represent the decrease in body temperature ± s.e.m. from the pre-injection baseline at 30 min after drug treatment, the time of maximum change. Rectal temperature was measured by insertion of a thermometer probe (Yellow Springs Instrument Company) 2.5 cm into the rectum. Values in parentheses represent number of animals tested.

*Ethanol-tolerant animals had been withdrawn from ethanol for 24 h.

†Values were compared by using Student's *t* test.

function, the dopamine-sensitive adenylate cyclase in brain was assayed for several days after ethanol withdrawal. Dopamine-sensitive adenylate cyclase activity was also measured in certain animals 8 h after a single i.p. injection of ethanol at 3 g per kg bodyweight. The brain section used for measurement of adenylate cyclase activity comprised the corpus striatum, diencephalon, and limbic areas[6]. This section was homogenised and assayed as described by Kebabian *et al.*[10] except that α-^{32}P-ATP was used as substrate and ^{32}P-cyclic AMP was isolated according to Saloman *et al.*[11]. The hypothermic effect of clonidine, an α-adrenergic agonist, was also monitored in both control and ethanol-tolerant animals.

Table 1 shows that animals which have been withdrawn from the ethanol-containing diet for 24 h were tolerant to the hypothermic effect of an acute dose of ethanol and were also less sensitive than controls to the hypothermic effect of piribedil. In contrast, ethanol-tolerant and control animals were equally sensitive to the hypothermic effects of the α-adrenergic stimulant clonidine. The change in the dose–response pattern of the hypothermic effects of piribedil in the ethanol-tolerant animals suggested a decrease in central dopaminergic receptor responsiveness to this agonist.

The dopamine-sensitive adenylate cyclase has been reported in most instances[12] to have many of the characteristics of the dopamine receptor *in vivo*[10, 13]. At 8 h after injection of a single dose of 3 g per kg ethanol, we found that basal adenylate cyclase activity and the stimulation of the enzyme by dopamine was similar in brains of ethanol-treated and control animals (that is at 10^{-5} M dopamine, the percentage stimulation over basal values was 66.8±9.1 (s.e.m.) in ethanol-treated and 66.4±3.9 in control animals). On the other hand, Fig. 1 illustrates the response of the dopamine-sensitive adenylate cyclase of mouse brain to various doses of dopamine in control animals and animals fed the ethanol-containing diet for 7 d and withdrawn for 24 h. The adenylate cyclase from the ethanol-tolerant animals showed a decreased response at all dopamine concentrations tested, and the response did not seem to reach the same maximum value as seen in control animals. Basal values were the same in control and ethanol-tolerant animals (see legend to Fig. 1).

The data in Table 2 demonstrate that the decreased sensitivity to the hypothermic effect of both ethanol and piribedil was still present at three days after ethanol withdrawal, but was no longer evident by 7 d after withdrawal. Similarly, dopamine-sensitive adenylate cyclase from ethanol-tolerant animals was significantly less sensitive to dopamine stimulation at three, but not at 7 d after withdrawal (see Table 2).

Seeber and Kuschinsky[14] have demonstrated that the dopamine-sensitive adenylate cyclase in brains of rats withdrawn from chronic barbiturate treatment was less responsive to dopamine stimulation than enzyme from control animals. These authors,[14] however, found little difference in response

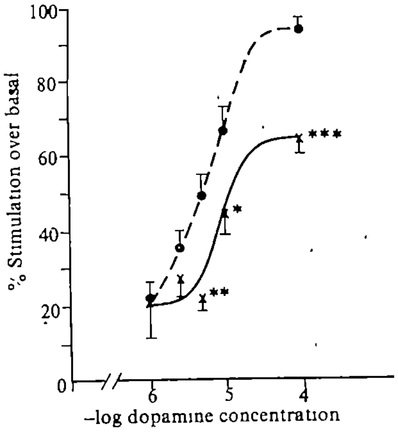

Fig. 1 Stimulation of dopamine-sensitive adenylate cyclase in brain of control (●) and ethanol-tolerant (×) animals. Animals were killed 24 h after withdrawal from the ethanol-containing diet, after 7 d of consumption. Brains were dissected and dopamine-sensitive adenylate cyclase activity was measured as described in the text. Basal values for control and ethanol-tolerant animals were not significantly different (respectively, 31.5±3.5 and 29.9±3.1 pmol cyclic AMP produced per 3 min). Dopamine concentration is molar, and results are expressed as per cent stimulation over basal values ± s.e.m. Values which are significantly different in ethanol-tolerant and control animals are indicated as follows: $*P < 0.05$; $**P < 0.01$; $***P < 0.001$ (*t* test).

to dopamine between ethanol-treated and control animals, but their animals were not shown to have developed any tolerance to ethanol, and the development of central nervous system tolerance may be critical for the observed alterations in adenylate cyclase activity.

Our finding that the maximal response of the adenylate cyclase to dopamine is decreased in ethanol-tolerant animals, while the concentration of dopamine producing a half-maximal response seems similar in both control and ethanol-treated animals, is in line with previous suggestions that changes in receptor sensitivity are related to alterations in receptor density rather than affinity for agonist[15,16].

We have recently demonstrated that partial destruction of brain noradrenergic systems by 6-hydroxydopamine (6-OHDA) before ethanol consumption blocked the development of tolerance to ethanol[17], but the same treatment administered

Table 2 Time course for the disappearance of ethanol tolerance and of alterations in dopamine receptor sensitivity

Drug	Time after withdrawal (d)	Change in body temperature Ethanol-tolerant	Control	P*
EtOH 3 g per kg	3	1.8±0.2 (6)	3.5±0.2 (6)	<0.05
	7	3.9±0.2 (6)	3.3±0.3 (6)	NS

Ethanol and piribedil were administered i.p. and body temperature monitored as described in the text and legend to Table 1. Dopamine-sensitive adenylate cyclase was measured as described in the text; basal values were similar to those in the legend of Fig. 1 and were not significantly different between ethanol-treated and control animals. All values represent mean ± s.e.m.; values in parentheses represent number of animals or, for adenylate cyclase activity, number of experiments.

*Values on any particular day were compared by the Student's *t* test.

after tolerance had developed did not prevent expression of tolerance[18]. Our previous data thus indicated that neurones other than those of the noradrenergic system would be responsible for the expression of tolerance to the hypothermic effects of ethanol. The postulated interaction between noradrenaline and dopamine-containing neurones[19], in which activity in one system could exert a modulatory influence on the other system, would lend support to a hypothesis that dopaminergic systems may be involved in expression of tolerance to the hypothermia produced by ethanol.

Although the time course of disappearance of decreased dopaminergic sensitivity seems to parallel the time course for disappearance of tolerance to ethanol, future studies should also evaluate the pattern of development of the alterations in dopamine receptor sensitivity, in order to more clearly define the possible relationship of such changes in the dopaminergic systems to the development of physical dependence on ethanol.

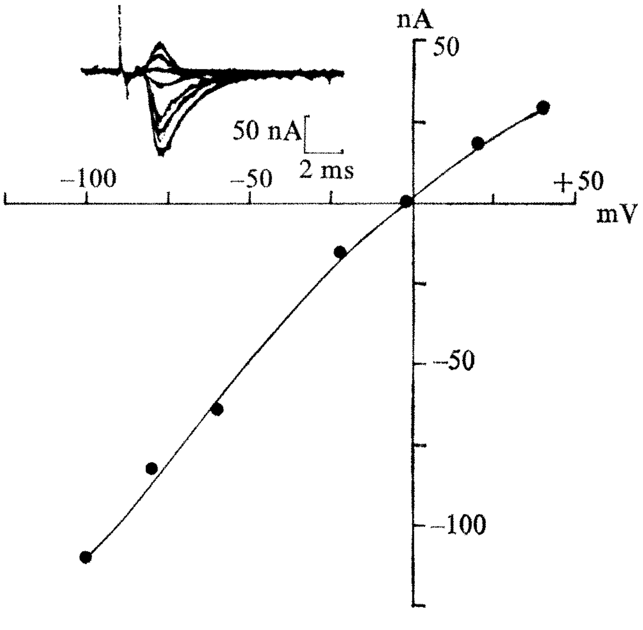
Desensitisation does not selectively alter sodium channels

WHEN depolarising drugs are applied to the endplate region of skeletal muscle fibres, the postjunctional membrane undergoes a rapid increase in ionic conductance. This increased permeability, largely for Na^+ and K^+, is slowly reversed if the agonist application is sustained. The gradual diminuition of response to agonist is due to endplate desensitisation[1]. Many factors influencing desensitisation have been described, but the molecular mechanisms responsible for the development of desensitisation remain unknown. Two fundamental types of mechanisms have been postulated to explain the phenomenon of desensitisation[2-6]. In the first, desensitisation is viewed as resulting from an alteration in the chemical receptor or binding site. The second type of mechanism suggests that desensitisation results from an alteration at some extrareceptor site such as that controlling the ionic channel in the endplate membrane. Kuba and Koketsu[7] have shown that the reversal potential for acetylcholine was shifted to more negative values at desensitised endplates. They argued that this change was due to a selective decrease in G_{Na} and therefore supported the view that an extrareceptor mechanism was important in the development of desensitisation. In contrast Koester[8] found no significant alteration in the reversal potential at desensitised endplates. In view of these conflicting observations we have re-investigated the question of whether there is or is not a selective alteration in endplate conductance during desensitisation. We report here that desensitisation does not selectively alter sodium channels.

All experiments were performed *in vitro* on sciatic nerve–sartorius muscle preparations from the frog, *Rana pipiens* maintained in a phosphate-buffered Ringers solution[6] or a Tris-buffered, Na^+-free, isotonic K^+ propionate solution[9]. For some experiments, the phosphate-buffered Ringers solution was made 2.3 times hypertonic by the addition of sucrose to minimise muscle contraction during carbachol application[6,10]. In other experiments, neuromuscular transmission was depressed by the addition of curare (2–3 mg l^{-1}) to the bathing solution to reduce the amplitude of the postjunctional conductance change. Endplate desensitisation was induced with carbachol. The carbachol was either added directly to the solution bathing the muscle preparation or was locally microperfused on to the endplate region of individual muscle fibres by hydrostatic pressure from an 85–100 μm diameter pipette placed within 50 μm of the recording and current-passing electrodes[6,10]. Junctional regions of individual fibres were located visually by following nerve twigs to the last node of Ranvier using transmitted light and a magnification of 300. Conventional electrophysiological techniques were used to measure resting membrane potentials. The neurally-induced endplate current (EPC) and carbachol-induced currents were determined with point voltage-clamp techniques using a two microelectrode voltage clamp similar in principle to that of Takeuchi and Takeuchi[11] and in detail to that described by Gibbons and Fozzard[12].

The possibility that desensitisation results in a selective decrease in Na^+ conductance at the endplate membrane was evaluated by comparing the reversal potential for neurally-evoked EPCs of curarised preparations to those of partially-desensitised endplates. We reasoned that a selective decline in Na^+ conductance during desensitisation would shift the reversal potential to a more negative value. Curare was used so that non-desensitised EPCs had similar amplitudes to desensitised non-curarised EPCs. Individual fibres were voltage-clamped over the range −100 mV to +40 mV, and the reversal potentials were determined by interpolation (Fig. 1). The reversal potential obtained from curarised (2–3 mg l^{-1}) junctions ($E_r = -2.4 \pm 2.8$

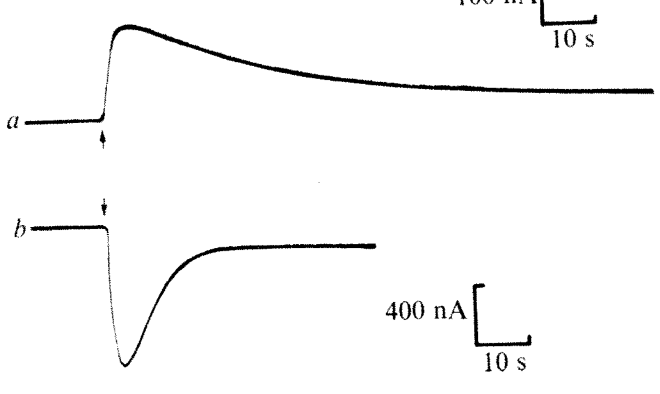
Fig. 1 Example of the current–voltage relationship obtained at a desensitised endplate. The muscle from which this record was obtained was bathed in a phosphate-buffered Ringers solution containing 55 μM carbachol. The data were gathered after exposing the muscle to carbachol for 25 min. In this particular fibre the resting potential was −44 mV. The inset shows the current traces from which the current–voltage curve was plotted. An upward deflection indicates outward current and a downward deflection indicates inward current. The EPC reversal potential, determined by interpolation is −2 mV.



mV; mean ± s.e., $n = 9$) was similar to that obtained from 55-µm carbachol-desensitised junctions ($E_r = -4.4 \pm 1.2$ mV; mean ± s.e., $n = 14$). This difference was not statistically significant ($P > 0.05$, Student's t test). These values of the reversal potential are comparable to those reported by others[13,14]. Estimates of the reversal potential were obtained during a 20–110-min exposure to curare or a 10–80-min exposure to 55 µm carbachol. In some carbachol-treated preparations there was a progressive decrease in the neurally-evoked EPC amplitude during this period whereas in other preparations the amplitude remained relatively constant during drug exposure. Nevertheless, the value of the reversal potential was similar in both instances. In the carbachol-treated fibres, the resting potential was initially low and progressively returned towards the pre-carbachol level with time[6]. This was taken as evidence for the continued development of desensitisation in these fibres.

If desensitisation selectively affects G_{Na} without influencing G_K, then carbachol-induced currents should not decay at E_{Na} where the EPC is primarily a potassium current. To test this possibility, the activation–desensitisation sequence was evaluated at E_K and E_{Na}. This was accomplished by monitoring the EPC produced by local microperfusion of 110 µM carbachol on to individual end plates voltage clamped at −100 mV or +50 mV, two values assumed to be reasonable approximations of E_K and E_{Na}, respectively. To minimise muscle contraction, these preparations were maintained in a hypertonic phosphate-buffered Ringers solution[10]. Microperfusion of 110 µM carbachol on to the endplate region of these voltage-clamped fibres induced a transient current superimposed on the holding current. At both voltages, the carbachol-induced EPC developed with time to a peak of a few seconds, then slowly decayed toward the pre-carbachol level even though the carbachol application was continued (Fig. 2). The decay of the carbachol-induced EPC indicates that desensitisation occurred at both E_K and E_{Na}. We have used the time constant of current decline as an index of the time course of desensitisation. In these two examples, desensitisation developed more slowly in the fibre voltage-clamped at +50 mV ($\tau = 38.6$ s) than in the other fibre voltage-clamped at −100 mV ($\tau = 7.0$ s). Similar results were obtained from three other muscle preparations, one fibre from each preparation being voltage-clamped at −100 mV and another at +50 mV during carbachol application. We attribute the difference in desensitisation rates at these two voltages to the voltage dependence of desensitisation as described by Magazanik and Vyskocil[4]; hyperpolarisation accelerating and depolarisation slowing the process.

Fig. 2 Time course of endplate current produced by sustained microperfusion of 110 µM carbachol. *a*, Response from an endplate voltage-clamped at +50 mV. *b*, Response from an endplate voltage-clamped at −100 mV. −100 mV and +50 mV were assumed to be reasonable approximations of E_K and E_{Na}, respectively. To minimise muscle contraction during carbachol microperfusion, these muscles were bathed in a phosphate-buffered Ringers solution made 2.3 times hypertonic by the addition of sucrose. Arrows indicate the onset of carbachol microperfusion. An upward deflection indicates outward current and a downward deflection indicates inward current.



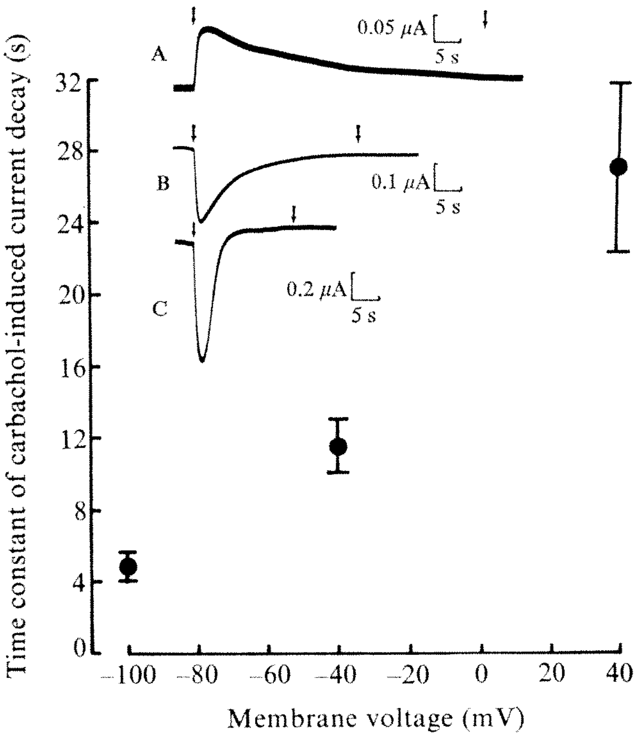


Fig. 3 Voltage dependence of desensitisation produced by 250 µM carbachol in K^+ depolarised muscle fibres. These data were obtained from fibres bathed in a Tris-buffered, Na^+-free, isotonic K^+ propionate solution. The time constant of carbachol-induced current decay during continued carbachol perfusion is plotted as a function of membrane potential. Each point represents the mean ± s.e. obtained from at least five fibres. The inset shows examples of 250 µm carbachol-induced currents from three different fibres measured in voltage clamp conditions. The fibres were voltage-clamped to: +40 mV (*a*), −40 mV (*b*), and −100 mV (*c*), respectively. Arrows indicate the onset and termination of carbachol application. An upward deflection indicates outward current and a downward deflection indicates inward current.

Desensitisation occurs in K^+-depolarised muscle preparations in the absence of extracellular sodium[9,10]. In these conditions, the agonist-induced current is carried primarily by K^+. We therefore evaluated desensitisation induced by local microperfusion of 250 µM carbachol in voltage-clamped muscle fibres (V_C at either −100 mV, −40 mV, or +40 mV) maintained in a Na^+-free, isotonic potassium propionate Ringers solution. Figure 3 indicates that the rate of desensitisation in these potassium depolarised fibres is voltage dependent, and the dependence is similar to that observed in polarised fibres (compare with Fig. 2). These observations indicate that the voltage dependency of desensitisation is maintained regardless of the ionic current-carrying species.

In agreement with Koester[8], we find no difference in EPC reversal potential between curarised and partially desensitised endplates. The data presented here suggest there is no selective alteration in G_{Na} at desensitised endplates. Because the current–voltage relationship for the EPC is nonlinear[13,14], estimates of the reversal potential obtained by extrapolation can be misleading. Although Kuba and Koketsu's[7] plots show little evidence of nonlinearity, this may account, in part, for the conflict between conclusions drawn previously by Kuba and Koketsu[7] and with those of Koester[8] and the present report. It should be noted that the experimental conditions used in this study and by Koester[8] are substantially different from those of Kuba and Koketsu[7]. In the former desensitisation was induced by applying carbachol to the bathing solution whereas in the latter desensitisation was produced by iontophoretic application of acetylcholine. Consequently, the different results may be due to different experimental conditions. But, in agreement with the data presented here, Manalis and Werman[15], using experimental conditions similar to those of Kuba and Koketsu[7], have demonstrated by interpolation that desensitisation does not alter the acetylcholine reversal potential. In summary, our results show that desensitisation develops whether the endplate current is carried mainly by Na+ and K+ or by Na+ and K+ individually, and that differences in time course of desensitisation apparently are due to the voltage dependence of the desensitisation process[4].

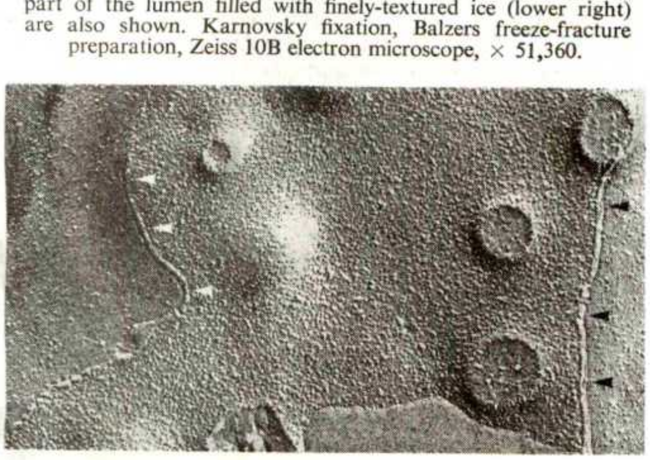
Significance of extensive 'leaky' cell junctions in the avian salt gland

Current models for hypertonic sodium secretion by salt glands assume there are physiologically tight junctions between the principal cells of the secretory tubules and that these cells actively secrete sodium across the cell membrane at the lumen in a one-stage process[1]. Our recent data require consideration of a new two-stage hypothesis concerning the secretory mechanism. Our freeze–fracture studies demonstrate that these cell junctions (*zonulae occludentes*) in the nasal salt gland of the herring gull (Fig. 1) should be classified as 'very leaky'[2]. Also, the extraordinary conformation of the apices of the principal cells within the epithelium makes these cell junctions most extensive (Fig. 2). Therefore, we propose that the salt glands of vertebrates produce their hypertonic effluent from the primary isotonic secretion of the peripheral cells at the ends of the secretory tubules, followed by the secondary reabsorption of water through the leaky junctions of the principal cells and not simply by the extrusion of Na+ across the luminal membranes of the principal cells. This new hypothesis is consistent with the accepted theories of sweat gland and salivary gland function, except that in the salt gland the second stage after isotonic secretion is water absorption, rather than salt reabsorption.

Fig. 1 Freeze–fracture image through the luminal membranes (*P*-faces) of three adjacent apical processes of the principal cells in the salt gland of a herring gull. It demonstrates clearly that the *zonulae occludentes* (arrowheads) are single-stranded. Circular profiles of the bases of several microvilli and a small part of the lumen filled with finely-textured ice (lower right) are also shown. Karnovsky fixation, Balzers freeze-fracture preparation, Zeiss 10B electron microscope, × 51,360.



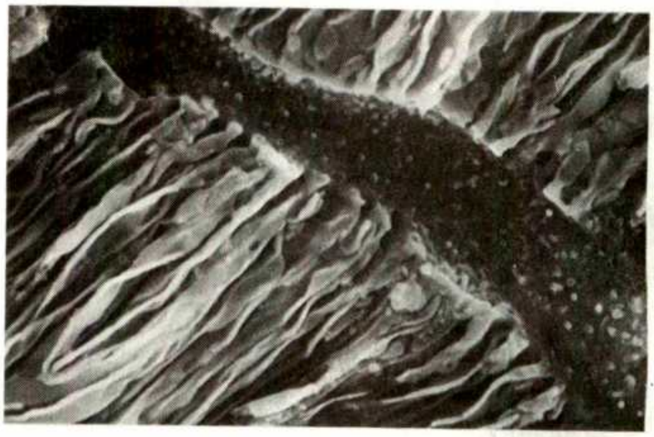


Fig. 2 The lumen of a secretory tubule from the nasal salt gland of a herring gull traverses diagonally from upper left to lower right through this scanning electron micrograph. Knoblike microvilli dot the surface of the lumen. The intermeshing apical processes of the principal cells form the wall of the lumen. Folded lateral surfaces of the principal cells (lower left and upper right) delimit long intercellular channels extending away from the luminal cell junctions. The complementary surfaces of overlying principal cells were pulled purposely out of their positions during specimen preparation. Karnovsky fixation, osmium-thiocarbohydrazide coating, critical point drying with CO_2, recorded with an AMR-1000 scanning electron microscope, × 5,928.

Within the salt gland the lobules contain branched, blind-ended secretory tubules (Fig. 3) that radiate from a central excretory canal[3]. The diameter of the lobules and the length of the secretory tubules are both directly correlated with the concentration of Na+ in the effluent of the gland[4]. Also, the size and height of the principal cells that predominate in these tubules increase progressively along a tubule from the periphery toward the centre of each lobule[5]. Within the cytoplasm of these cells large, abundant mitochondria are closely associated with the lateral membranes along the intercellular channels[6]. In addition, cytochemical[7–10] and autoradiographic[11] studies show that the enzyme system responsible for sodium transport is found in these lateral plasma membranes and not in the luminal membranes of these cells.

In contrast, the cuboidal peripheral cells (Fig. 3), situated in the blind end of each tubule are relatively small. They resemble closely the 'clear' secretory cells that are found in the secretory tubules of eccrine sweat glands, and have cytochemical[12,13] and ultrastructural[6] characteristics that are quite different from the principal cells.

Freeze–fracture images (Fig. 1) through the plasma membranes at the luminal interface of principal cells show that the *zonulae occludentes* consist of a single strand. Thus, by comparison with other epithelia[2], this junction must be classified as very leaky. This classification is substantiated also by earlier tracer studies on salt glands[14,15].

The strikingly complex plicated lateral surfaces of the principal cells in the secretory tubules of the salt gland of the herring gull is revealed by the scanning electron microscope (Fig. 2). Folds of these membranes form the boundaries of long intercellular channels that extend from the apical cell junctions to the extracellular space at the base of the epithelium. In addition, the complicated intermeshing at the lumen of the apical ends of the principal cells[6], means that the leaky cell junctions are unusually extensive.

Figure 3 shows our conception of how a secretory tubule

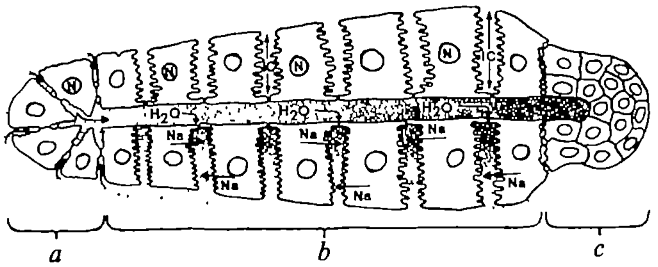

Fig. 3 In this diagram of a single secretory tubule in a salt gland, the number of cell junctions as well as the complexity of the intercellular channels are greatly reduced, and the diameter of the lumen of the tubule is much enlarged. The terminal segment (*a*) of the tubule is composed of small peripheral cells; the remainder of the tubule (*b*) is lined by principal cells. The central excretory canal (*c*) is continuous with an excretory duct (not shown). The intercellular channels (IC) are closed at their luminal ends by leaky cell junctions. The density of the stipple in the lumen and in the intercellular channels indicates the concentration of Na$^+$.

produces a hypertonic secretion. Isotonic fluid secreted by the peripheral cells at the terminal cul-de-sacs (*a*) flows along the lumen of the tubule towards the central canal (*c*). As this secretion moves over the apices of the principal cells that line most of the tubule (*b*), water is absorbed from this fluid through the leaky junctions between the principal cells and into the intercellular channels where a standing gradient[16] of Na$^+$ is maintained by the sodium pumps in the lateral membranes of the cells. Na$^+$ ions are most concentrated at those ends of the channels near the leaky cell junctions that border the lumen of the tubule and are least concentrated at the bases of the channels where they are open to the subjacent extracellular space. In maintaining the standing gradient, NaCl is recycled by the principal cells. NaCl enters the cells from the blood across the basal membrane, is pumped out the lateral membrane into the intercellular channels, and then returns to the blood. The NaCl moves from the blood into the cell, passing down a concentration gradient created by the lateral extrusion pumps. As a consequence of this standing gradient, water flows from the lumen into the intercellular channels. The concentration of Na$^+$ in the fluid that remains in the lumen of the tubule will approach the maximum of the standing gradient that is achieved in the intercellular channels. Accordingly, the height of the principal cells, and hence the length of the intercellular channels, along with the level of operation of the Na$^+$ pumps, produce also a standing gradient within the lumen of the tubule and affect the Na$^+$ concentration of the final effluent. Simply stated, the principal cells do not secrete the hypertonic effluent of the glands. Instead, water is passively reabsorbed through the leaky cell junctions from the isosmotic fluid that is secreted by the peripheral cells. This differs from the original form of the standing gradient hypothesis[16] which postulated water flow across the apical and lateral cell membranes.

This hypothesis requires that NaCl extruded laterally into the intercellular spaces is recycled NaCl, and does not come from the lumen, also that the plasma membranes of the principal cells must be relatively impermeable to water. This latter requirement is not unique, since cells with similar properties are found, for example, within the loop of Henlé in the mammalian kidney. It is also consistent with experimental data on intercellular osmolarity in salt glands[17,18]. In addition, extracellular coats that are detectable at the surface of the principal cells[14, 19] might also affect the permeability of the membrane.

Our hypothesis solves the dilemma of the orientation of the sodium pumps. Localisation of the sodium pumps along the basal and lateral membranes[7–11] required under earlier hypotheses[1] that Na$^+$ be pumped into the cells, an unprecedented orientation. In this new hypothesis, the sodium pumps have their usual outwards orientation and still have a role in hypertonic secretion.

Composition of sarcoplasmic reticulum *in situ* by electron probe X-ray microanalysis

EXCITATION–contraction (E–C) coupling in striated muscle[1,2] involves depolarisation of the surface membrane that propagates through invaginations of the surface membrane, the transverse tubular (T) system, to the interior of the fibre. Stored Ca is then released from the adjacent sarcoplasmic reticulum (SR), and activates the contractile proteins. The mechanism of release of Ca from the SR is not definitely known, although it is thought to be triggered by the T-tubule action potential either through electrical coupling, possibly involving voltage dependent charge movement[3–5] across the T-SR foot processes[6–7] and depolarisation of the SR[2,8,9] and/or a chemical coupling involving a Ca induced Ca release[9–12]. Depolarisation of the sarcoplasmic reticulum in skinned muscle fibres by Cl induces Ca release[2]. The evaluation of the various models of E–C coupling requires some knowledge of whether the ionic distribution across the SR membrane can give rise to a potential and, specifically, whether the content of the SR resembles that of the extracellular or of the intracellular fluid. So, to measure the ionic composition of individual elements of the sarcoplasmic reticulum *in situ*, we used electron probe X-ray microanalysis of frozen–dried thin section of a fast striated muscle The data we report here show that neither Cl nor Na are compartmentalised in the SR, and that their concentrations in the SR (on a dry weight basis) do not differ from those in the surrounding cytoplasm. Ca was found to be sequestered in the sarcoplasmic reticulum confirming other studies (refs 13, 14 and see refs 1, 2 for reviews). These findings (albeit on a dry weight basis) do not support the existence of a Cl or Na potential across the SR membrane in resting muscle.

The swimbladder muscle of the toadfish *Opsanus tau* is a very fast twitch muscle with a time to peak contraction of 5–8 ms and an extraordinary development of the sarcoplasmic reticulum[15]. The extent of the SR (approximately 30% of fibre volume, C. Franzini-Armstrong, personal communication) and its very regular arrangement of two triads per A band (Fig. 1) make it very suitable for viewing in unfixed frozen-dried thin sections. The muscles were shot into supercooled Freon 22, sectioned at −130 °C and

Region analysed	Na	P	S	Cl	K	Ca	Mg
Cytoplasm (between SR)	30±4.3	275±2.0	335±2.0	47±1.1	510±2.7	4±0.8	47±1.9
Sarcoplasmic reticulum	34±4.2	443±2.5	362±2.0	42±1.0	589±2.8	77±0.9	40±1.8

Values are means ± s.e.m., $n = 25$ pairs. We used a Philips EM 301 transmission electron microscope with a goniometer stage modified to accept a 30-mm^2 (20° specimen to detector angle, 0.067 sr solid angle, 160 eV resolution) Kevex Si(Li) X-ray detector interfaced with a Kevex 5100 multichannel analyser and a Tracor Norther NS 880 computer and TN 1,000 magnetic tape recorder. A modified Philips liquid nitrogen cooled holder, operated at −100 to −110 °C, was used to minimise contamination and mass loss. The detailed characteristics of the system have been described previously[19]. Some analyses were done with the Philips EM 400 operated with an LaB$_6$ source and interfaced as above. The better vacuum (2×10^{-7} torr) allowed us to obtain longer counts without contamination and the higher brightness of the LaB$_6$ source yielded a higher count rate. The probe diameters were 50–100 nm. The SR was probed in regions adjacent to the T-tubules where these could be identified. The regions of the cytoplasm analysed were within 200 nm of their respective SR pairs. The measurement of elemental concentrations is based on the fact, pointed out by Hall[18], that for elements of atomic number $Z \geq 11$–20 in concentrations of less than 1 mol per kg, the characteristic peak/X-ray continuum ratio is linearly related to the concentration/dry mass. The peak counts in the unknown peak and its error of measurement are computed together with the counts in the continuum band 1.34–1.64 keV. The basic equation for quantitation is $C_x = (I_x/I_b)\chi\, W_x$, where C_x is the concentration of element χ, I_x is the number of characteristic peak counts for that element, I_b is the number of continuum counts and W_x is a quantitation parameter relating concentration to peak/background ratio and is obtained from standards. W_x includes the effects of ionisation cross sections, fluorescence yield and detector efficiency for each specific element.

The X-ray spectrum obtained in a transmission electron optical column from a thin section includes the characteristic peaks due to elements $Z \geq 11$ present in the specimen and the associated continuum largely arising from the organic matrix. It also contains instrumental peaks (the largest one being the Cu signal $K_\alpha = 8.047$ keV) from the specimen grid and holder, with an associated extraneous continuum, and low energy noise probably due to electrons reaching the detector. These extraneous signals and the associated continuum can be measured by collecting the spectrum generated with the beam passing through an empty grid hole, and are subtracted by the computer routine as is the low energy noise[19].

freeze–dried as reported previously[16]. Frozen–dried thin sections of unfixed muscle are shown in Fig. 2 and can be compared with a conventionally glutaraldehyde-osmium fixed section of the same muscle shown in Fig. 1. The junctional gap between the T-tubule and terminal cisterna[6,7] is also present in the unfixed frozen sections, but the T-tubule is not as flattened as in fixed material (Fig. 2*b*). The longitudinal SR is narrower in the cyro sections and has a laminated appearance, suggesting that measurements in conventionally fixed material may give rise to overestimates of the *in vivo* SR volume. A collapsed longitudinal SR has been previously observed in frog striated muscles fixed in the presence of polyvalent cations[17] and in freeze–fracture replicas of unfixed muscle (Franzini-Armstrong, Reese and Heuser, personal communication).

The concentrations of Na, P, S, Cl, K, Ca and Mg in, respectively, the SR or the adjacent cytoplasm (25 paired analyses with 50–100 nm probes) are shown in Table 1. Because the quantitation is based on the ratio of the characteristic peak to the X-ray continuum counts[18,19] from frozen–dried material, the data are expressed as mmol per kg dry weight. The mean Ca concentration in the SR of resting muscle is 77 ± 0.9 (s.e.m.) mmol per

Fig. 1 Longitudinal section from a toadfish swimbladder muscle fixed in glutaraldehyde, post fixed in osmium and embedded. T-tubules indicated by arrows. (× 41,580).

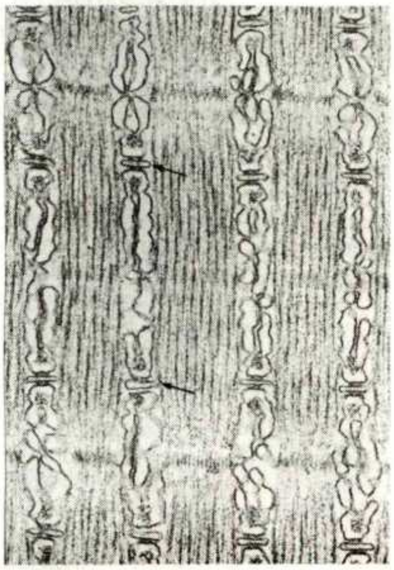

Fig. 2 Longitudinal cryo sections from toadfish swimbladder muscle. The muscle mounted on a low mass stainless steel mesh holder was frozen by shooting it into supercooled (−164 ± 2 °C) Freon 22 and sectioned at −130 °C in a modified LKB cryokit. The sections were picked up dry onto Cu grids with carbon foils, dried at < 10^{-6} torr overnight, carbon coated and stored dessicated. This section was stained with osmium vapour under vacuum to enhance contrast. Electron probe X-ray microanalyses were generally done on similar but unstained material. A detailed description of the freezing and cryoultramicrotomy is given elsewhere[16]. T-tubules are indicated by arrows. Circles indicate the approximate probe size used for the analyses summarised in Table 1. *a*, × 39,960. *b*, × 53,680.

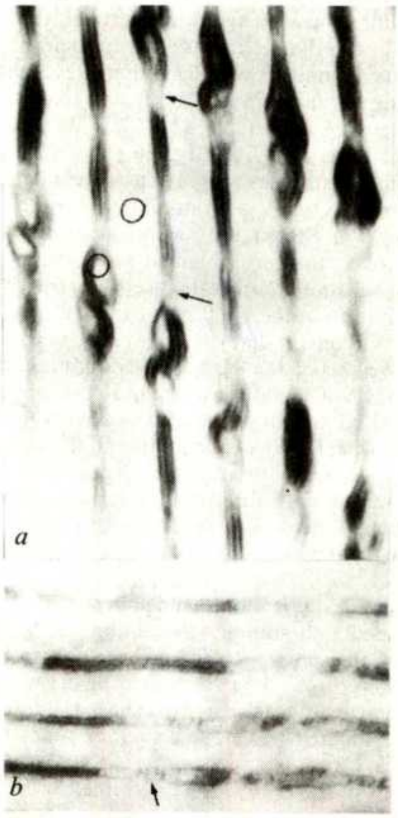

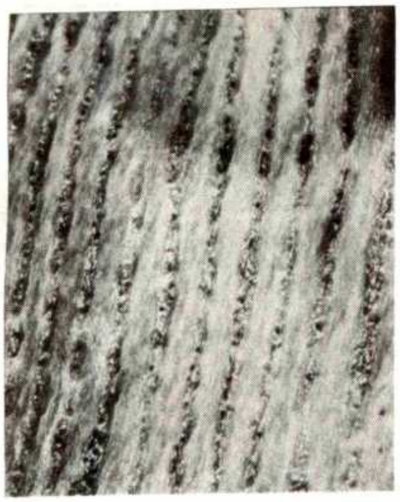

Fig. 3 Longitudinal cryo section from a damaged toadfish swimbladder muscle fibre. Unstained. The sarcoplasmic reticulum is loaded with electron dense granules. (× 4,650.)

kg. Because much of the phosphorus in the SR region (Table 1) could be within membrane phospholipids, these experiments do not indicate whether P (phosphate) is a counterion for Ca. The Ca concentration in the regions of cytoplasm between the SR shown in Table 1 was higher than in frog muscle[16]. This may reflect some overlap of obliquely oriented SR in the narrow segments of cytoplasm analysed (Fig. 2) and/or Ca binding to the parvalbumins in fish muscle[20]. Recent studies, however, indicate that the parvalbumin contents of frog and fish muscle are similar[24].

The Na and the Cl concentrations in, respectively, the SR and adjacent cytoplasm were not significantly different. This finding does not support the existence of a Na or Cl potential across the SR membrane, however, electron probe analysis of freeze–dried cryo sections measures total (bound and free) ion contents rather than activities. The greater (by approximately 80 mmol per kg) concentration of K detected over the SR than over the cytoplasm is similar to our observations on frog stiated muscle SR[16] and could arise from differences in hydration between the two regions or from K binding to the SR and its acidic proteins[21,22].

The results of analyses of 1–6 μm diameter areas that included both SR and cytoplasm (in 13 fibres from 4 toadfish) were: (mmol per kg dry weight ± s.e.m.): Na, 42 ± 7.2; P, 360 ± 4.3; Cl, 56 ± 1.9; K, 539 ± 5.1; Ca, 26 ± 1.6; Mg, 36 ± 3.0. The relatively high (26 ± 1.6 mmol per kg dry weight) Ca content detectable with the probe parameters used is primarily due to the large volume occupied by the SR in the swimbladder muscle. The other elemental concentrations obtained with these large diameter probes also substantiate the absence of 'extracellular' ion compartmentalisation in the SR (apart from Ca), shown in Table 1. The bulk NaCl content that would have been expected (277 mmol per kg dry weight) on the basis of an SR containing extracellular fluid (231 mM NaCl) and constituting 30% of fibre volume is very much higher than the measured values (Na, 42 ± 7.2; Cl, 56 ± 1.9 mmol per kg dry weight). Minor differences between these Na and Cl concentrations and those measured with small probes (Table 1) were due to fibre-to-fibre variations. The Na and Cl concentrations measured with large (1–6 μm) or small (50–100 nm) probes in the same fibre were not significantly different.

In one damaged fibre not included in the tabulated results, the SR was loaded with granules containing Ca, Mg and P (Fig. 3). Analyses of this fibre with large diameter probes showed Ca concentrations of 76 ± 3.5 m mmol per kg dry weight indicating a threefold increase in total fibre Ca. The maximum Ca capacity of the SR is estimated to be three to four times greater than its physiological Ca content[2,23].

The results of this study are in agreement with our findings on frog striated muscle[16], that the Cl concentration of the SR does not approach extracellular levels. In addition, the results on toadfish SR show a similar absence of compartmentalised Na; this excludes the possibility that the relatively low Cl concentration in the SR is due to Donnan exclusion by acidic proteins. We conclude that the T–SR junction in resting muscle is not freely permeable to Na or Cl.

We thank Dr Clara Franzini-Armstrong for suggesting the use and making a gift of some toadfish and for comments on the manuscript. We also thank Mr John Silcox for technical assistance. This work was supported by grants from NHLBI (to the Pennsylvania Muscle Institute) and from NIGMS 00092.

Myoblast myosin phosphorylation is a prerequisite for actin-activation

CYTOPLASMIC myosins are found in most non-muscle cellular systems studied to date[1]. In vertebrates these myosins are composed of two heavy chains of 200,000 molecular weight (MW) and four light chains, two each of 20,000 and 15,000 MW. A number of cytoplasmic myosins, as well as skeletal, smooth, and cardiac muscle myosin, can be enzymatically phosphorylated[2–6]. That is, those light chains of MWs 18,000–20,000, the so-called P-light chains[6], can undergo phosphorylation catalysed by a myosin light chain kinase[7,8]. In this reaction the terminal phosphate of ATP is transferred to a specific amino acid residue on the myosin P-light chain, up to one mole of phosphate per mole of light chain[9,10]. A myosin light chain phosphatase that catalyses the removal of the covalently-linked phosphate group from the P-light chain, returns the myosin to the non-phosphorylated state[5,11]. Phosphorylation of human platelet myosin[4], guinea pig vas deferens[3] and chicken gizzard[12,13] smooth muscle myosin results in an increase in the actin-activated ATPase activities of these myosins. Although the phosphorylation of the P-light chain of rabbit skeletal muscle myosin has been described[10], no functional change in this myosin's activity due to phosphorylation has been demonstrated[11]. To study the role of myosin phosphorylation during muscle cell differentiation, we investigated precursor cells to skeletal muscle, namely proliferative myoblasts. The Yaffe

L-5 810 line of cloned proliferative rat myoblasts is an actively dividing cell line in culture which under the appropriate conditions can form myofibrils. We now report: (1) that myosin isolated from proliferative myoblasts contains light chains of 20,000 and 15,000 MW, (2) the 20,000 MW light chain can be phosphorylated by an endogenous myosin light chain kinase[14], (3) the proliferative myoblast myosin light chain kinase does not require calcium ions for activity, and (4) phosphorylation is a pre-requisite for actin activation of the myosin's ATPase activity.

Myosin and the myosin light chain kinase were isolated from 3 g of proliferative rat myoblasts by extraction at high ionic strength (0.5 M KCl, 15 mM Tris-HCl (*p*H 7.5), 10 mM $Na_4P_2O_7$, 10 mM dithiothreitol (DTT), 1 mM EDTA), followed by dialysis against low salt (0.05 M KCl, 10 mM Tris-HCl (*p*H 7.5), 5 mM DTT, 0.1 mM EDTA) to form a precipitate and sedimented at 48,000*g* for 10 min. The pellet was suspended in 3 ml of 0.5 M KCl, 15 mM Tris-HCl (*p*H 7.5), 1.0 mM EDTA, 2.5 mM DTT (protein concentration 5–10 mg ml^{-1}) and then made 10 mM in MgATP and fractionated with ammonium sulphate.

When the 35–55% saturation ammonium sulphate fraction was dialysed to remove the ammonium sulphate and then incubated with $MgAT^{32}P$, incorporation of ^{32}P was observed in the fraction as is shown in Fig. 1. Aliquots of the phosphorylated fractions at different times of incorporation were electrophoresed in 1% sodium dodecylsulphate (SDS)–7.5% polyacrylamide gels, stained for protein, and the entire gel was cut into slices which were then counted for ^{32}P. As Fig. 1 shows, within 30 min 0.8 mol of ^{32}P were incorporated per mol of P-light chain. Thus it was determined that an endogenous myosin light chain kinase was present in the proliferative myoblast actomyosin fraction.

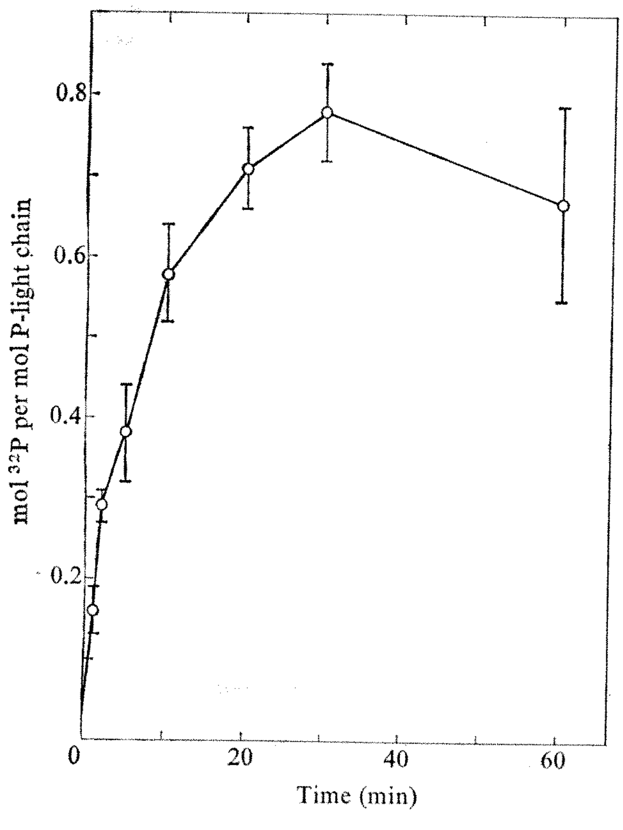

Fig. 1 Time course of ^{32}P incorporation into the proliferative myoblast myosin P-light chain by the endogenous myosin light chain kinase. The 35–55% saturation $(NH_4)_2SO_4$ fraction of actomyosin was dialysed against 0.5 M KCl, 15 mM Tris-HCl (*p*H 7.5), 2.5 mM dithiothreitol (DTT), 1 mM EDTA and incubated in the phosphorylation conditions: 0.2 M KCl, 30 mM Tris-HCl (*p*H 7.5), 12.5 mM $MgCl_2$, 5 mM DTT, 0.2 mM $CaCl_2$, and 0.1 mM ATP. The ATP was premixed with $Na_4\gamma$-$AT^{32}P$ (30 Ci $mmol^{-1}$) so as to give 200,000 d.p.m. in 5 µl of the final mixture (0.4 ml). The reaction was stopped by the addition of SDS to a final concentration of 1% and 0.05% $Na_4P_2O_7$. These samples were then dialysed to equilibrium against 0.3 M, 0.2 M, 0.1 M NaCl, and finally deionised water to remove the excess $AT^{32}P$. 1% SDS–7.5% polyacrylamide gel electrophoresis was carried out as described previously[16] with the exception that diallyltartardiamide (BioRad) was substituted for *bis*-acrylamide in the same molar ratio to the acrylamide[17]. The P-light chain was cut out of the gel and dissolved with 2% periodic acid and then counted in ACS (Amersham/Searle) scintillant. The data are for four determinations from three different preparations ± s.d.

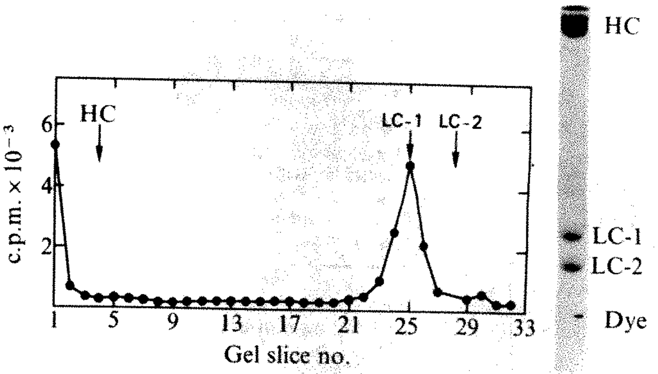

Fig. 2 Incorporation of ^{32}P into column-purified proliferative myoblast myosin with column-purified proliferative myoblast light chain kinase. Unphosphorylated myoblast actomyosin (35–55% $(NH_4)_2SO_4$ fraction) was made 10 mM in MgATP immediately before fractionation on a Sepharose 4B column (1.5 × 90 cm), which was equilibrated and eluted with 0.5 M KCl, 15 mM Tris-HCl (*p*H 7.5), 1 mM EDTA, 2.5 mM DTT. The 4 °C temperature, high ionic strength (0.5 M KCl), and speed of application of the sample to the column were necessary to inhibit phosphorylation in the unphosphorylated actomyosin. The myosin and myosin light chain kinase eluted as distinct peaks, were pooled individually, and then aliquots were mixed in the phosphorylation conditions and processed for gel electrophoresis as in Fig. 1, except that 5 µl of the final mixture gave 40,000 d.p.m. There were 3 µg of the P-light chain on the gel. The myosin light chain kinase fraction was purified only partially by gel filtration. But, only catalytic amounts of this fraction were used for the phosphorylations, as can be discerned by this gel, since no band at 80,000 MW characteristic of either the skeletal[7] or platelet[8] kinase can be detected. In similar experiments, the samples were treated with RNase, which eliminated the counts at the top of the gel, but did not change the incorporation into the 20,000 MW light chain. HC, myosin heavy chain (200,000 MW); LC-1, myosin light chain one, the P-light chain (20,000 MW); LC-2, myosin light chain two (15,000 MW).

Gel filtration of the 35–55% ammonium sulphate fraction on Sepharose 4B resulted in separation of purified myosin from the kinase (see refs 5, 3 for similar results with platelet and smooth muscle actomyosin). An SDS–polyacrylamide gel of such a pooled myosin fraction is shown in Fig. 2. The apparent MWs in SDS of the light chains were 20,000 (LC-1) and 15,000 (LC-2), similar to other proliferative myoblast myosin[15]. When this purified myosin fraction was incubated with the myosin light chain kinase fraction from the same column in the phosphorylation conditions (see Fig. 1 legend) and then electrophoresed on an SDS–polyacrylamide gel, incorporation of ^{32}P was seen only in the 20,000 MW light chain, the P-light chain. The amount of incorporation depicted in this figure is 0.76 mol of ^{32}P per mol of P-light chain. As controls, these two fractions were incubated separately in the phosphorylation conditions and subjected to gel electrophoresis as in Fig. 2. No incorporation was seen in either of these fractions.

A major difference between the kinase present in rat proliferative myoblasts and adult rat thigh muscle is shown in Table 1. Whereas the adult rat muscle kinase requires Ca^{2+} for its activity, the myoblast kinase does not. In this respect the myoblast myosin light chain kinase is of the cytoplasmic type, similar to those of human platelet[8] and mouse astrocytic neuroglial myosin[2]. The rat thigh muscle kinase is similar to that of rabbit skeletal muscle in requiring Ca^{2+} for activity[7].

The effect of phosphorylation on the specific ATPase

Table 1 Effect of calcium on the activity of the myosin light chain kinase

Kinase	Substrate	mol ^{32}P incorporated per mol P-light chain $+Ca^{2+}$	$-Ca^{2+}$
Proliferative myoblast	Myoblast myosin	0.75	0.81
	Skeletal myosin light chains	0.91	0.86
Rat thigh muscle	Skeletal myosin light chains	0.93	0.01

Either proliferative rat myoblast or adult rat thigh muscle myosin light chain kinase was column-purified as described in Fig. 2. These kinases were then incubated for 60 min under the phosphorylation conditions ($+Ca^{2+}$) as in Fig. 1 or in the presence of 2 mM EGTA ($-Ca^{2+}$) with native myoblast myosin or myosin light chains from rabbit skeletal muscle isolated from a 35–55% $(NH_4)_2SO_4$ fraction according to the method of Perrie and Perry[18]. All the values are calculated from 1% SDS–10% polyacrylamide gels as described in Fig. 1.

activities of phosphorylated and unphosphorylated proliferative myoblast myosin is shown in Table 2. To obtain phosphorylated and unphosphorylated myosin the 35–55% ammonium sulphate fraction was divided in half and was either phosphorylated or incubated without ATP and then chromatographed on a Sepharose 4B column. The purified myosin was pooled and the ionic strength was lowered to 20 mM KCl by dialysis. No actin activation of the myosin ATPase activity at low ionic strength (0.017 M KCl) can be demonstrated for the unphosphorylated myosin (Table 2). But a 9–12-fold increase in the myosin ATPase with actin is seen for the phosphorylated myosin. No effect of phosphorylation was seen on the high salt (0.5 M KCl) ATPase activity of myosin alone. Therefore, phosphorylation specifically affects the actin interaction with myosin.

Table 2 also demonstrates that even though the actin concentration is tenfold greater than the myosin concentration (mg per mg), there is no increase in the actin-activated ATPase activity on the addition of actin to unphosphorylated myosin. Using platelet myosin[4], a small amount of actin-activation of the myosin ATPase activity in the control (unphosphorylated) sample has been observed. In that work, it was unclear whether this actin activation was due to a small amount of phosphorylation or was a property of the non-phosphorylated myosin. In this report we show that before phosphorylation no actin activation of the myosin ATPase activity occurs (see Table 2) indicating that in the proliferative myoblasts, myosin phosphorylation is a prerequisite for actin activation. Further Table 2 shows that there is no difference in the actin-activated ATPase activity of phosphorylated myosin measured in the presence of Ca^{2+} and EGTA. This is similar to the results reported for phosphorylated platelet myosin[5], but differs from the findings for vas deferens myosin[3].

Table 2 The effect of phosphorylation on proliferative myoblast myosin ATPase activity

	Actin-activated ($+Ca^{2+}$)* $-$Actin	$+$Actin
Phosphorylated	0.015	0.175
Unphosphorylated	0.018	0.019
	Actin-activated ($-Ca^{2+}$) $-$Actin	$+$Actin
Phosphorylated	0.019	0.181
Unphosphorylated	0.020	0.022
	Myosin alone† K^+–EDTA	Ca^{2+}
Phosphorylated	1.31	0.218
Unphosphorylated	1.28	0.225

Specific activity is expressed as µmol Pi per mg myosin per min at 37 °C. The standard deviations of these values are less than or equal to 15%. Actomyosin fractions of proliferative rat myoblast myosin (see Fig. 1) were divided in half. One half was phosphorylated and the other half was incubated in the phosphorylation conditions without ATP. These fractions were then column-purified (see Fig. 2). These fractions gave similar electrophoretic patterns to those of Fig. 2. The data presented are from six determinations on four different preparations. Inorganic phosphate liberation was measured by a modification of the method of Martin and Doty[4,20]. In some experiments phosphate release was measured as ^{32}P released from AT^{32}P using the same method[20], but without the development of colour. Protein concentrations were estimated by the method of Lowry *et al.*[21] using bovine serum albumin as a standard.

*Assay conditions: 17 mM KCl, 10 mM Tris-HCl (*p*H 7.4), 1 mM ATP, 1.4 mM $MgCl_2$, 0.1 mM $CaCl_2$ ($+Ca^{2+}$) or 1 mM EGTA ($-Ca^{2+}$). Myoblast myosin 0.04–0.10 mg ml^{-1}, rabbit skeletal muscle actin[19], 0.4–1.0 mg ml^{-1}.

†Assay conditions: 0.5 M KCl, 20 mM Tris-HCl (*p*H 7.4), 2 mM ATP, and either 2 mM EDTA or 10 mM $CaCl_2$. Myoblast myosin, 0.04–0.07 mg ml^{-1}.

Myosin phosphorylation has been demonstrated previously to increase the actin-activated ATPase activity of platelet and smooth muscle myosin. The extension of this regulatory system to proliferative myoblasts, as well as the identification of myosin light chain kinase in astrocytic neuroglial cells[2] and HeLa cells (J. A. Trotter, S.P.S. and R.S.A., unpublished) suggests that myosin phosphorylation is a general regulatory mechanism controlling the actin–myosin interaction in both non-muscle and smooth muscle cells.

We thank Drs W. Uhlendorf and G. Cantoni for providing the myoblasts, J. M. Miles for technical assistance and E. Murray for typing the manuscript. S.P.S. is a postdoctoral fellow of the Muscular Dystrophy Association of America.

A synthetic polypeptide with antifreeze activity

MUCH information has been gathered in recent years on the so-called 'antifreeze' proteins which lower the freezing point of the serum of certain marine fishes living in sub-zero water temperatures[1–4]. The proteins from the Antarctic fish *Trematomus borchgrevinki* are glycoproteins with a repeating alanyl-alanyl-threonyl tripeptide sequence, the threonyl residue being linked to a disaccharide[1,2]. In contrast, the antifreeze protein from the winter flounder *Pseudopleuronectus americanus* in the North American Atlantic coastal region is made up of eight amino acids with no apparent repeating sequence of the residues and no sugar moiety (ref. 4 and unpublished work of C. L. Hew, C. C. Yip & G. Fletcher). The antifreeze activity of these proteins is not compatible with the known colligative properties of solutes in solution and the mechanism of their action is not yet fully understood. But a common feature of both types of the antifreeze proteins is the preponderence of alanine which accounts for over 60% of the total amino residues. This fact, together with the absence of the carbohydrate in the protein from the winter flounder, prompted us to attempt the synthesis of polypeptide analogues having comparable proportions of alanine in them along with suitable other amino acids. As a first step, we made use of the lack of any obvious periodicity in the distribution of the alanyl residues in the flounder's protein and attempted the synthesis of a random copolypeptide containing about 65 mol % of alanine and 35 mol % of aspartic acid. The choice of aspartic acid was made on the basis of its being the next major amino acid in the flounder's protein[3,4] and on the expectation that its polar character will help the water-solubility of the alanine-rich copolypeptide, as in other studies on alanine-containing random copolymers. In addition, Duman and DeVries[4] have earlier indicated the involvement of carboxyl groups on the antifreeze activity by chemical modification studies. We report here the synthesis of this polypeptide and show that it possesses antifreeze activity.

The copolypeptide was synthesised by first polymerising the *N*-carboxyanhydrides of L-alanine and β-benzyl L-aspartic acid in the molar ratio of 65 : 35 respectively in dioxane with triethylamine as the initiator; the β-benzyl group of aspartic acid was then removed by using either anhydrous hydrogen bromide[6] or hydrogenfluoride–pyridine[7]. The products from both these procedures were very similar in their properties including the antifreeze activity.

Table 1 Properties of the synthetic polypeptide

Sample no.	Composition (mol 1 %)* Alanine	Aspartic acid	Molecular weight†	α-helical content‡
SAF-I§	65.5	34.5	45,000–70,000	15
SAF-II¶	64.8	35.2	50,000–70,000	20

*Determined on a Beckman Model 121M amino acid analyser after 24–48 h of hydrolysis in 12 M HCl at 110 °C. The compositions of the polypeptides before deblocking the side-chain benzyl group, were almost identical to those of the final products.

†Estimated using a Sephadex G-75 column calibrated with protein markers.

‡Estimated on the basis of the circular dichroism data as before[8].

§Synthesised using HF–pyridine debenzylation method.

¶Synthesised using the HBr debenzylation method.

Table 1 summarises the data on the amino acid composition, molecular weight distribution and α-helical content of the synthetic polypeptide. Compared with the flounder's protein, the synthetic analogue is found to have a larger average molecular weight and a much lower α-helical content: the molecular weight of the protein is about 10,000 and its α-helical content about 85% (ref. 8).

Figure 1 shows the antifreeze activity of the synthetic polypeptide plotted as a function of its concentration in 0.01 M KCl, *p*H 6.0: the corresponding data for the flounder antifreeze protein are also shown. The synthetic polypeptide is apparently 'active', that is, like the antifreeze proteins, it depresses the freezing point of the solution to a far greater extent than can be accounted for in terms of its colligative property. This is illustrated by the data shown in Fig. 1 for serum albumin (molecular weight 68,000), which does not exhibit any antifreeze activity. Other globular proteins like myoglobin and cytochrome *c* were also inactive. An interesting feature of the data in Fig. 1 is the indication of a plateau in the activity of the synthetic polypeptide at higher concentrations, again very similar to what is observed with the protein counterparts (refs 1 to 4 and unpublished work of C. L. H., C. C. Yip & G. Fletcher). The magnitude of the antifreeze activity of the synthetic analogue is about one-third that of the flounder's protein at a given concentration. The decreased activity of the synthetic polypeptide when compared with the protein may be due to the differences in their amino acid compositions, sequences and molecular weights as well as the secondary structure. But the fact that such a simple model polypeptide can, albeit partially, mimic the natural protein in its function, seems to indicate the importance of the predominance of alanine in all the known antifreeze proteins. While we do not have an immediate answer as to the role of either the alanyl or aspartic residue in the mechanism of action of these proteins, a systematic study of the properties of the synthetic polypeptide analogues will, as pointed out by Feeney[1], prove to be valuable in our understanding of these proteins. Such a study is now in progress in our laboratories.

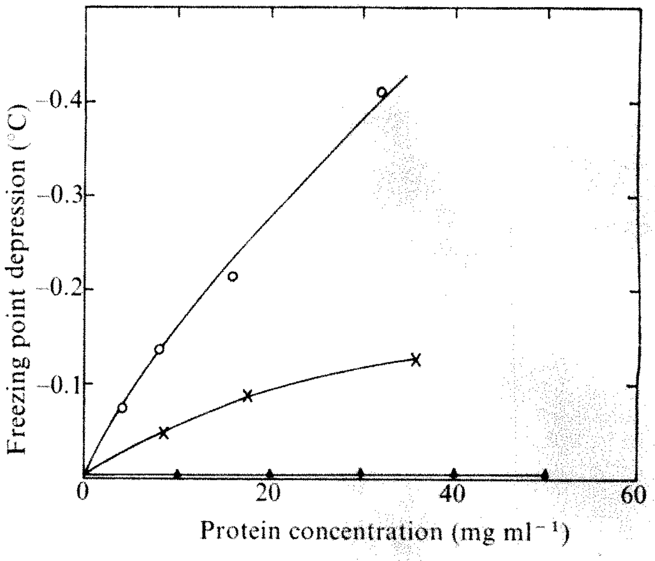

Fig. 1 Antifreeze activity of the synthetic random copolypeptide (×), SAF-I as a function of its concentration. The sample was dissolved in about 0.5–1.0 ml of 0.01 M KCl, *p*H 6.0, to yield the highest required concentration and dialysed extensively against the same solvent. The activity was determined as depression of the freezing point of the solution, using an Advanced Instruments model 3-R osmometer. Correction was made for the KCl in the solvent. The concentration of the polypeptide was determined by using $E^{1\%} = 18$ at 230 nm (ref. 8). The antifreeze activities of the flounder's protein (○) (unpublished work of C. L. H., C. C. Yip & G. Fletcher) and albumin (▲) are shown for comparison.

This work was supported by grants to C.L.H. from the MRC of Canada and the Banting Research Foundation; V.S.A. thanks the Canadian Commonwealth Fellowship Committee for a fellowship. We thank Professor C. Bigelow for laboratory facilities and Mr N. Liunardo for technical assistance.

Effect of light on artificial lipid membranes modified by photoreceptor membrane fragments

THE molecular basis of photoreception has been extensively studied, but it is not yet clear which of the photolysis products of rhodopsin has the key role in receptor potential generation. Penn and Hagins[1] have shown that the effect of an absorbed photon persists for about 0.1 s at 33 °C (rat retina). If metarhodopsin II is the key product, as most workers assume it to be, then the result of Penn and Hagins can be explained as follows. On formation of metarhodopsin II a visual pigment molecule undergoes a transformation with time constant 0.1 s, which 'cuts-off' the process of visual excitation. Metarhodopsin II persists for dozens of seconds at 33 °C (as determined from spectral characteristics[2]) so if the suggested transformation takes place it should not result in variations of the absorption spectrum of metarhodopsin II, and thus could not be detected by spectroscopy. As the artificial lipid membrane (ALM) is a good detector of changes in functionating protein molecules[3–5], we attempted to detect the above process by examining the photoeffect on ALM, modified by photoreceptor membrane components.

Such an approach seems to be verified also by the fact that rhodopsin is a typical membrane protein, and investigation of the above model might give information useful for understanding the mechanisms of receptor potential generation. We used ultrasonicated rod outer segment fragments (ROSF) for the modification.

ROSFs were obtained by ultrasonic treatment of ROS suspension in distilled water. The membranes were formed using the method of Mueller *et al.*[6] on a hole (1-mm diameter) of a Teflon cup placed in a glass chamber. The lipid solution used contained egg lecithin (18 mg ml^{-1}) and cholesterol (12 mg ml^{-1}) in heptane. The modification was carried out in the solution containing ROSF (absorbance 0.15 at 500 nm). The solutions on each side of the membrane were the same in all cases. A current through ALM was measured using an electrometer amplifier (Keithley model 301) in voltage-clamp conditions. The capacity of the modified ALM was two to three times lower than that of unmodified membranes (membrane capacity was evaluated from the time constant of the current recording circuit). The dark d.c. resistance of both modified and unmodified membranes was of the order of $5\times10^{10}\,\Omega$. 1-ms flashes from a xenon discharge tube were used to illuminate ALM.

The response of the modified membrane to a light flash is shown in Fig. 1 which shows that a flash brings about an increase of current through the membrane. A characteristic feature of the response is its reversibility—an increase of the current is followed by a spontaneous drop to the dark level. In the conditions of illumination used (bleaching of no less than 80% or rhodopsin), the effect could be observed only once for each modified membrane: repeatedly flashed white-light illumination caused no photoelectric current. Illumination by red light (beyond 650 nm) affected neither the current through the membrane, nor its ability to respond to a subsequent illumination by white light. In unmodified membranes, no photoeffect could be observed.

Further investigation of the photoeffect has shown the following:

(1) The effect was independent of purity of the preparations. In the case of low-purity ROS (the purity criterion measured according to Heller[7] being about 4.0), the membrane response was the same as with pure preparations (purity about 2.2). This indicates that a substance responsible for photosensitivity of ALM is contained in the outer segment.

(2) The direction of current through the membrane was determined by the applied voltage, and its magnitude always increased in response to light. At zero applied voltage, there was no current and no response. These facts show that the illumination of ALM brings about an increase in the membrane conductivity rather than the appearance of a photo-electromotive force, which had been observed for membranes containing carotenoids[8,9].

(3) Hydroxylamine at 100 mM did not change the observed photoeffect.

(4) A steady-state conductivity of a modified membrane was generally somewhat higher after illumination than before illumination.

(5) The photoeffect was observed, with no significant changes, in 100-mM NaCl and in 100-mM KCl (both solutions buffered with 10-mM imidazole/HCl, *p*H 6.25). The addition of Ca^{2+} to these solutions at 10 mM did not produce any detectable changes in the photo-induced conductivity. Addition of Ca^{2+} at higher concentrations resulted in a rapid aggregation of ROSF.

Investigation of the photoeffect in ALM at various temperatures gave the following results:

(1) The time constant of the photo-induced increase in the ALM conductivity was, within experimental error, the same as the period of formation of metarhodopsin II, cited in the literature (refs 10 and 11). An activation energy of the process was about 30 kcalorie mol^{-1}.

(2) The rate of the subsequent decrease in the model membrane conductivity depended on temperature according to the Arrhenius' law, with activation energy 19 ± 3 kcalorie mol^{-1} (Fig. 2). From the extrapolation of the Arrhenius' plot to 33 °C, the time constant of the process was evaluated to be 80 ± 10 ms. Our data thus indicate that in the modified ALM light induces a process with time constant close to the duration of "a photon effect" as determined by Penn and Hagins[1]. The observed return of the model membrane conductivity to a near dark level may therefore be con-

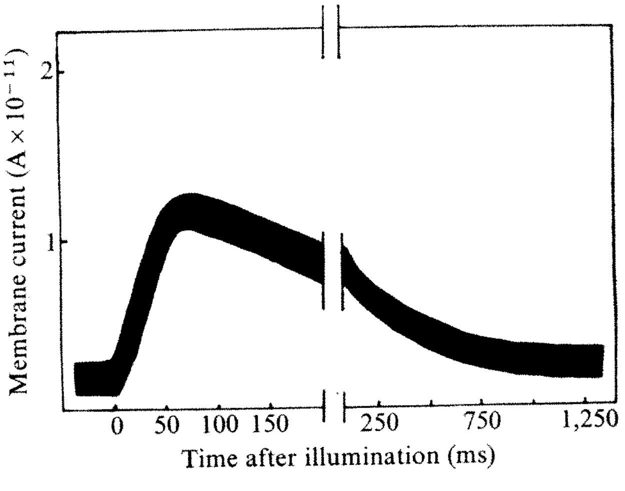

Fig. 1 The effect of illumination on artificial lipid membrane modified by ROSF. Conditions: 100 mM NaCl, 10 mM imidazole/HCl, *p*H 6.25; 17 °C. Voltage across the membrane, 100 mV. Recording time constant for the current flowing through the membrane—about 2 ms. ROS were isolated as follows: retinae, excised from dark-adapted cattle eyes, were put in isoosmotic buffer solution (140 mM NaCl, 3.5 mM KCl, 1.8 mM CaCl$_2$, 0.5 mM MgCl$_2$, 10 mM Tris, *p*H 7.4) identical to that used by Korenbrot and Cone[13], 1 ml per retina, and subjected to mild homogenisation on a magnetic stirrer for 20 min. The homogenate was centrifuged for 10 min at 100*g*. The supernatant was collected and centrifuged for 10 min at 10000*g*. The sediment was suspended in 40% (w/v) sucrose solution prepared in the isoosmotic buffer and subjected to flotation for 30 min at 30,000*g*. The flotation was repeated twice. To determine the optical density and the purity criterion, the ROS were solubilised with 2% solution of cetyl trimethylammonium bromide.

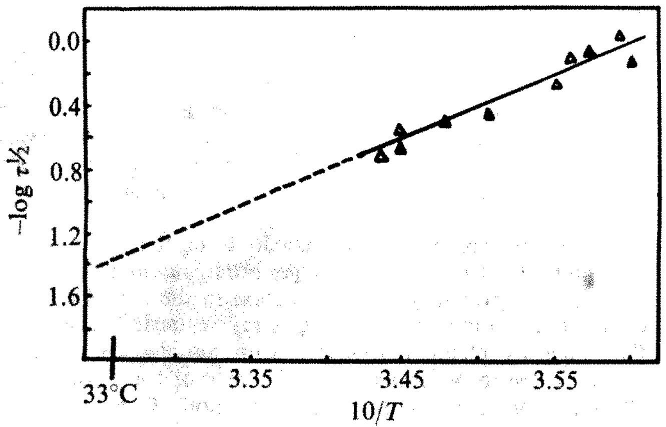

Fig. 2 Temperature (T) dependence of period (in seconds) required for the return of model membrane conductivity to half-maximum level ($\tau_{1/2}$).

nected with a 'switching off' of a mechanism inducing the receptor potential of a rod. No definite conclusions could be made as to the nature of the process involved, however. The mechanism probably involves either a conformation transition in rhodopsin after the formation of metarhodopsin II, or a rearrangement of photoreceptor membrane occurring, following a certain delay, after the formation of metarhodopsin II.

What is the mechanism of the observed photoeffect? The answer would depend on which situation was realised in our experiments—whether visual pigment molecules (or disk membrane fragments) are included in ALM, or ROSF in the shell form are simply sorbed at the model membrane. If the former is true, then our data apparently indicate that rhodopsin can modulate photoreceptor membrane permeability. In that case, one could suggest the simple realisation of a transmitter scheme of the photoreceptor function (for example, see ref. 12): a short-period photoinduced increase in the disk membrane permeability results in the release of a quantity of mediator capable of changing the permeability of ROS plasma membrane. If the latter version is the case, the variations in ALM conductivity most probably do not represent changes in disk membrane conductivity, and the model membrane would act only as a detector of rearrangements in visual pigment and (or) its lipid surroundings.

As yet it is impossible to make a choice between the two alternative mechanisms of photoeffect observed.

Effect of aminoacylation on the conformation of yeast phenylalanine tRNA

MUCH effort has been devoted to analysing the effect of aminoacylation on the structure of transfer ribonucleic acid (tRNA). While it is generally held that changes in conformation provide the basis for the discrimination between acylated and nonacylated tRNA in tRNA: aminoacyl tRNA synthetase, tRNA: ribosome and tRNA: co-repressor interactions, the evidence to support this view to date is in serious conflict. We have been using the technique of laser light scattering to investigate the tertiary structure of tRNA (ref. 1). This technique is particularly well suited for analysing structural changes in macromolecules such as tRNA as it can detect changes of as little as 1% in the translational diffusion constant. The method has the advantage of allowing rapid, continual data monitoring making it possible to study dynamic changes in conformation. We describe here the use of this technique to monitor the diffusion coefficient of aminoacylated tRNA in conditions where deacylation occurs spontaneously. The results clearly demonstrate that: (1) large changes in the conformation of yeast phenylalanine tRNA do occur on aminoacylation, (2) the change can be reduced to an undetectable value by small changes in the solution parameters, and (3), the results apparently provide an explanation for many of the discrepancies observed by others.

Figure 1 shows the results obtained when phenylalanyl-tRNA was allowed to deacylate in the two different solution conditions. When the tRNA was in 10 mM Mg^{2+}, $D_{20,w}$ increased linearly from 7.46×10^{-7} cm^2 s^{-1} at 555 pmol per A_{260} to 7.79×10^{-7} cm^2 s^{-1} at 35 pmol per A_{260}. In this condition, the half-time for deacylation was 71 min. A least squares fit to these data yields an overall change in $D_{20,w}$ of $4.6 \pm 0.6\%$ with an extrapolated change of $14 \pm 2\%$ starting with pure, fully aminoacylated tRNA. On the other hand, when deacylation was allowed to occur in 1 mM $MgCl_2$ the values of $D_{20,w}$ showed no change as the extent of acylation decreased from 620 pmol per A_{260} to less than 1 pmol per A_{260}. In this condition the half-time of deacylation was 55 min. The slope of the plotted line was calculated to be zero within limits of error ($-0.5 \pm 0.9\%$).

The results show that the diffusion constant for yeast tRNA$^{\rm Phe}$ increases on deacylation in 10 mM Mg^{2+}. This change indicates that deacylation results in the formation of a more compact structure than that which obtains for the aminoacylated conformer. This interpretation agrees with results of Kaji and Tanaka[2] which indicated that aminoacylated *Escherichia coli* tRNA$^{\rm Phe}$ sediments slower than the uncharged species.

Of the interpretations consistent with our observations, the most plausible are that aminoacylation results in: (1) a disruption of secondary base pairing with resultant changes in secondary and tertiary structure or (2) changes in tertiary structure alone owing to a disruption of tertiary base pairing and/or an alteration in the distribution of counterions. The possibility that the observed changes in $D_{20,w}$ for tRNA$^{\rm Phe}$ in 10 mM Mg^{2+} is simply due to the addition of a molecule of phenylalanine can be ruled out due to the large magnitude of the change. The first interpretation also seems unlikely in light of results from a number of circular dichroism studies performed under a variety of solution conditions which indicate that no changes occur in the secondary structure on aminoacylation[3–6].

Alteration of the tertiary structure alone thus seems most plausible and while the results of this experiment do not allow us to specify the portion(s) of the tertiary structure involved in the change, results from other studies provide some insight. Two studies have shown increased steroid[7] and polycytidine[8] binding to the aminoacylated form of many tRNAs. Both ligands selectively bind guanosine residues suggesting that aminoacylation exposes the pair of guanosine residues which occur in the dihydrouridine loops of nearly all tRNAs[9]. In addition, results from studies on the binding of complementary tetranucleotides to yeast $tRNA^{Phe}$ strongly suggest that residues in the dihydrouridine and pseudouridine loops are exposed on aminoacylation[10].

Other results indicate that changes can also occur in the region of the junction of the D-stem and amino acid acceptor stem. Differences were found in the circular dichroism band associated with 4-thiouracil when the spectra of charged and uncharged *E. coli* $tRNA_F^{Met}$ were compared[11]. EPR studies with *E. coli* $tRNA^{Phe}$ have shown a difference on aminoacylation of the rotational correlation times from a spin label attached to 4-thiouracil[12].

Taken together, these results suggest that aminoacylation may result in the disruption of tertiary base pairs between the dihydrouridine and pseudouridine loops and rearrangement of the 'L' structure to a less compact conformation. An apparent exception to this interpretation comes from results of a nuclear magnetic resonance study which showed no changes in hydrogen bonding of yeast $tRNA^{Phe}$ on aminoacylation[13]. This study was performed at *p*H 5.0, however, a condition in which others could not detect a change in sedimentation behaviour on aminoacylation[14].

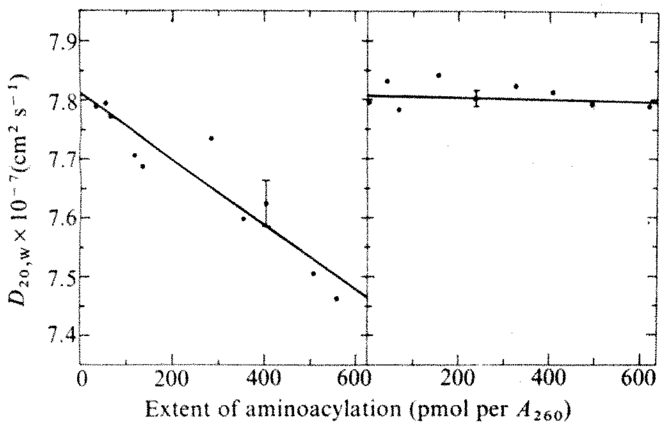

Fig. 1 Translation diffusion constant ($D_{20,w}$) of yeast $tRNA^{Phe}$ as a function of the extent of aminoacylation. Phenylalanine tRNA with an acceptor activity of 850 pmol per absorbance unit (A_{260}) was aminoacylated with ^{3}H-phenylalanine (200 mC mmol^{-1}) in a reaction mixture that contained, per ml: 25 µmol Tris-HCl, *p*H 7.2, 12.5 µmol $MgCl_2$, 4 µmol ATP, 5 nmol ^{3}H-phenylalanine, 2 nmol $tRNA^{Phe}$ and sufficient phenylalanyl-tRNA synthetase to allow complete charging in 15 min at 37 °C. When acylation was complete, 0.1 volume of 20% potassium acetate, *p*H 4.5, was added to the reaction mixture and the aminoacyl-tRNA repurified by chromatography on a small column of DEAE–cellulose. The tRNA was precipitated with ethanol, recovered by centrifugation, dried under vacuum and stored at −20 °C until use, usually within 18 h. In a typical experiment, 5 A_{260} (250 µg) of charged $tRNA^{Phe}$ were solubilised in 25 µl of 1 mM sodium acetate, *p*H 4.5 and dialysed against the same buffer with 1.0 or 10 mM Mg^{2+}. One-fifth volume of a 5 × stock of the appropriate buffer was then added: 8 µl of the sample were filtered into a 1 × 1 × 45-mm cuvette for light scattering; the remainder was filtered into a test tube thermostatically maintained at the same temperature (20 °C). Portions of the larger sample were withdrawn at various times, acidified with trichloroacetic acid and the acid-insoluble radioactivity collected on glass fibre filters to determine the extent of deacylation. Details of the procedures used in the purification of the tRNA and synthetase, the preparation of the ^{3}H-phenylanyl-tRNA and the preparation of the tRNA for light scattering will be described elsewhere. The techniques for data collection and analysis have been described[1]. The concentration of tRNA for the experiment done with 10 mM Mg^{2+} was approximately twice that used for the measurement taken at 1 mM Mg^{2+}. Hence, extrapolation of the diffusion constant values to zero tRNA concentration would yield a higher value with 1 mM Mg^{2+} than with 10 mM Mg^{2+}. That extrapolation was not done here because an unknown, but constant amount of stray light was present due to the very small size of the cuvettes used for the measurements. The effect of stray light is to lower observed diffusion constant values by about 2% for every 1% of stray light present and is more significant at low concentrations of tRNA where the relative contribution by the stray light increases. These effects were not important in the large cuvettes used in previous experiments[1]. Measurements were made at 20 °C for samples in 0.01 M Tris-HCl (*p*H 7.2), 0.1 M NaCl with 10 mM $MgCl_2$ and 6.2 mg ml^{-1} tRNA (*a*) or 1 mM $MgCl_2$ and 3.0 mg ml^{-1} tRNA (*b*). Each point represents an average of at least six determinations made within a 10-min period. Values of diffusion constant are normalised to 20 °C and the viscosity of pure water. Error bars represent ±1 s.d. (σ) about the point; σ showed little variation during the experiment, with values consistently less than 0.3% of $D_{20,w}$.

Less likely, because of the magnitude of the effect, is the possibility that the observed changes occurring on aminoacylation are due primarily to an alteration in the distribution of counterions. Ninio *et al.*[15] using X-ray scattering, concluded that intensity changes attendant with aminoacylation were probably due to perturbations in the layer of counterions—an effect eliminated at low Mg^{2+} concentrations. Consistent with this view, Cohn *et al.*[16] found that the number of manganese binding sites changed with aminoacylation. Thus, it is possible that aminoacylation results in minor rearrangements of structure which alter divalent cation binding sites. This in turn could affect the distribution of counterions and hence, the diffusion constant. These interpretations are also consistent with the negative results obtained in a number of studies designed to detect changes in secondary structure[3–6,13,17–19].

The results presented here do not allow us to discriminate between changes in tertiary structure and/or counterion distribution. It is, however, possible to determine the contribution of each effect on the diffusion constant by performing this experiment at various concentrations of tRNA and salt. These experiments are in progress. The present results vividly demonstrate the importance of Mg^{2+} ions in structural changes of $tRNA^{Phe}$ on aminoacylation. Magnesium ions have been implicated previously in structural changes of deacylated $tRNA^{Phe}$ (ref. 1); however, this is the first clear evidence that the conformational changes which occur on aminoacylation/deacylation are altered by magnesium. The results also suggest that specific changes in intracellular magnesium levels might have a central role in regulation of tRNA function.

matters arising

The Star of Bethlehem

I WOULD like to make a brief comment on David Hughes's article on the Star of Bethlehem. While the astronomical phenomena are described with vivid precision, the historical aspect would merit equal attention. Dionysius Exiguus is surely thought to have placed the Annunciation at 25 March 1 BC and the Nativity therefore at 25 December 1 BC and not AD 1. I quote from E. J. Bickerman[1] in support of my view that Dionysius' supposed 5-yr error is at best an irrelevance (page 77 of ref. 1).

> An era *ab urbe condita* (from the founding of the city of Rome) did not in reality exist in the ancient world, and the use of reckoning the years in this way is modern. . . . The principal reason for not using the system *ab urbe condita* was that the age of the city was disputed: *est enim inter scriptores de numero annorum controversia* (Cic. *Brut.* 18, 72). The date of the founding in Roman historiography—excluding the more extreme opinions—oscillates between 759 and 748 BC.

Of 58 modern authors cited by Holzmeister[2], 33 select for the year of the Nativity 7–5 BC, so Hughes represents majority modern opinion. Of 42 ancient opinions listed, however, not one falls as early as this period and only one before the supposed date of Herod's death. A thorough re-examination of the date of the Nativity must also ask whether it is certain that Herod died in 4 BC. Josephus states that Herod reigned 34 years from the death of his predecessor, executed by Antony some time after the capture of Jerusalem which fell in 37 BC. The obvious arithmetical error is accounted for by the explanation that Josephus counted the year in which a king died and the (same) year of the accession of his successor as two separate years, and therefore, overestimated the length of each reign by 1 year—his so-called 'inclusive' method.

Although this notion of Josephus' mode of computation is the pillar on which the modern opinion rests, no shred of evidence is adduced for it, for there is none. Evidence to the contrary is, however, easily found in *Jewish Antiquities*. Between February 135 BC and October 63 BC there were in Jerusalem six rulers in the 72 years 8 months. Summing the lengths of reigns as given by Josephus, we have 71 years 6 months. This is very exact and certainly evidence that Josephus did not reckon 'inclusively'.

Since Herod died shortly after a lunar eclipse, the times are restricted in which his death could have fallen. 4 BC is too early to allow for a reign of 34 years (if the 'inclusive' method of counting is rejected) and there were no such eclipses in 3 or 2 BC. It is then hard to escape from the conclusion that Herod died following a partial eclipse in 9/10 January 1 BC having completed 34 years' reign a few months earlier. Just before the eclipse, there was an uproar in the Temple recorded by Josephus, and possibly unleashed by the advent of the Magi if the traditional date of the Adoration, 6 January is again considered.

[2] Holzmeister, U. *Chronologia Vitae Christi* (Rome, 1933).

HUGHES'S suggestion that the 'Star of Bethlehem' was probably a triple conjunction of Saturn and Jupiter in the constellation Pisces in 7 BC was anticipated by Stauffer in 1957 (*Jesus: Gestalt und Geschichte*). The significance of this *'coniunctio magna'* was explained as follows: Jupiter was the 'star' of the world ruler and the constellation of the fishes as the sign of the last days; the planet Saturn was considered in the east to be the 'star' of Palestine. So the conjunction indicated, not a 'Jewish king born in Israel', but that in that year there would appear in Palestine the ruler of the world in the last days.

As long ago as 1835 D. F. Strauss observed the evangelist's contrived story to show fulfilment of the prophecy of Micah that the ruler of Israel should come from Bethlehem, and claimed "we have absolutely no guarantee that Bethlehem was his birth-place" (*The Life of Jesus Critically Examined*, SCM ed. 1973, p 156). Guignebert concluded that the magi, star, massacre of innocents, birth in a stable, shepherds, angels, and so on, are all unhistorical and that we do not know where Jesus was born, except in Galilee. He also noted that the idea that the Jewish population had to move all over the land to register for the taxation was "outside the plane of reality" (*Jesus* 1935, pp. 94 & 99). Mackinnon noted the 'assumption' that enrolment required the parents of Jesus to journey to Bethlehem for this purpose, and did not believe the stories of the magi and the massacre of infants (*The Historic Jesus*, 1931, pp. 19 & 24). More recently, Gunther Bornkamn, in his *Jesus of Nazareth* (1951) says hardly anything about the birth, infancy or early years of Jesus. He claims that the birth and infancy stories of Matthew and Luke are largely legendary in character and do not contribute to a *History* of Jesus.

All that we know about Jesus is that he was born in Galilee. If he was about 30 years old (Luke III, 23) when John baptised him in Tiberius's 15th year (Luke III, 1) then it looks as if he was born in the terminal year, and that the chronology of Dionysius Exiguus is correct. We know of no reason why this should not have been so, and there is no cause to believe the stories associating the birth with celestial signs or the Roman registration of 6 CE.

Incidentally, Dionysius did not "forget the year zero"; there was no such year, as demonstrated by Hughes's own chart!

STUART CAMPBELL

KEPLER may not have been the first to be impressed by a Jupiter–Saturn appulse[1]. In the chronicles of Worcester Priory (1377) a conjunction in Aquarius was recorded in 1285—"it had not happened since the Incarnation". Newton[2] comments that this suggests that the Star "had already been interpreted as a conjunction by AD 1285". It could be a rhetorical expression.

The object of −5 (6 BC) is regarded by Stephenson[3] as a comet, because there is a possible reference to a tail and motion and certainly there does not seem to be any remnant known.

CICELY M. BOTLEY

[2] Newton, R. R. *Mediaeval Chronicles and the Rotation of the Earth* 691 (John Hopkins University Press, Baltimore and London, 1972).

[3] Stephenson, F. R. *Q. Jl R. astr. Soc.* **17**, 12 (1976).

I COMMENT here on two points made by David Hughes. First, there seems to be no need for a year zero because from our standpoint, in 1976, any year in which Jesus Christ was born, be it spring or autumn, was 1 AD—"the first year of the Lord," and the preceding year 1 BC—"the first year before Christ." Perhaps the author thinks of

1 AD as the first year after the birth of Christ.

Second, for those of us who hate to believe that St Luke or any Holy Scripture could have been "mistaken", or at least so easily written off as such, perhaps Cyrenius and Quirinius are not one and the same.

With no year zero to account for between 1 BC and AD 1, the author's second scenario seems more likely to conform to fact.

HUGHES, in his article on the Star of Bethlehem, makes life unnecessarily difficult for himself. He estimates that a journey of 550 miles across the desert, from Sepharuaim to Jerusalem would have taken four months in preparation and travelling. Consequently he has to show that the triple conjunction of Jupiter and Saturn in Pisces would have been visible, in varying positions, throughout that period of time.

T. E. Lawrence, writing of the Arab Revolt in *Seven Pillars of Wisdom*, recorded that a fully loaded camel, under an experienced rider, could, if hard pressed, cover 80 to 100 miles in a 24-hour period, depending on the country, and that 50 miles ridden in the same period was considered a holiday by comparison. Even the most inexperienced and clumsy riders, who positively hindered their animals, could travel 30 miles a day. The length of stages undertaken in the crossing of a desert is limited, of course, by the distance between wells, but even so, the Magi could have completed their journey from Babylonia in 2 weeks at the outside, or in 10 days with less comfort. Allowing 2 weeks for preparation (gathering of stores, hiring of men and beasts and so on), the whole enterprise would have taken a month at the most.

In other words, the Magi not only could have set off when the triple conjunction was at its best, but would also have been in a position to respond to signs of a much more transient nature.

HUGHES[1] convincingly dates Jesus' birth by astronomy to 7 BC but unfortunately rejects the historical evidence in Luke II, 2, as usually found in English versions, when an equally valid and grammatically justified alternative translation can be used to support his theory. Luke II, 2 is usually translated [illegible] the first enrolment when Quirinius was governor of Syria"[2]. An enrolment, or census, under Quirinius is well documented because of a subsequent rebellion[3–5], but Quirinius was not governor until AD 6–9. Thus, Luke seems to contradict both the astronomy and Matthew (II, 1), who says Jesus was born before Herod the Great died, that is, before 4 BC.

The necessary change, which completely alters Luke's evidence depends on the use of the Greek word *protos*, usually translated 'first'. *Protos* is the superlative derived from *pro*, meaning before, the comparative being *proteros*, meaning former or sooner. Consequently, according to strict grammar, *protos* should mean first of at least three. But the Hellenistic Greek used in New Testament times was at least as relaxed as modern English in which 'first' is often used when 'former' or 'prior' would be more grammatical[6]. Thus, 'first enrolment' in its Hellenistic connotation is 'first of two' or 'one before' and, as Bruce[7] suggests, Luke II, 2 is best translated "This enrolment was before that made when Quirinius was governor of Syria". Similar expansions, in which words need to be supplied in translation, are not uncommon and there is no grammatical reason against supplying them in this passage[6].

Numerous Egyptian papyri of a slightly later date indicate that enrolments occurred every 14 years (ref. 3). If this 14-year interval was observed in Syria the enrolment before that of Quirinius would have been sometime between 9 and 6 BC. Thus, Luke II, 2, instead of being dismissed as a mistake, can be used to support the date deduced by Hughes.

HUGHES REPLIES—The significance of the triple conjunction of Jupiter and Saturn in the constellation of Pisces[1] around 7 BC can be beter judged by reference to Fig. 1. At no time do the planets approach closer than 1 °, about twice the diameter of the full moon. All the stars in this region pale into significance in comparison with the brightness of the two planets (see Fig. 2).

'Herod' was a fairly common name in those times. Herod the Great, the son of Antipater, was made the Governor of Galilee anud afterwards titular King of Palestine by the Romans. On his death the kingdom was divided between his three sons, Archelaus, Herod Antipas (who received Galilee) and Herod Philip II. There is very little doubt that Jesus was born during the reign of Herod the Great (Matthew II, 22) and was tried and crucified during the reign of Herod Antipas (Luke XXIII, 8, Matthew XIV, 1); however, some biblical chronologists do cast doubt on the generally accepted superstition that Herod the Great died between 13 March and 11 April 4 BC, as Edwards shows above.

Simmons finds the month of the birth of Christ by relating the lives of Christ and John the Baptist (personal communication). Zacharias, the father of John the Baptist, was a priest of the course of Abia (Luke I, 8) and would have served in the temple during the 6th week after Passover, the week before Pentecost. As all the priests also served during Pentecost, Zacharias would have left Jerusalem for his home town around Sivan 12th (15 June). Elizabeth, his wife, conceived soon after his return (Luke I, 24) so John the Baptist would have been born about 280 days later, around 27 March. Luke (I, 36) records that Christ was 6 months younger than John the Baptist so this puts the birth of Christ in late September. Interestingly we read in the Talmud that sheep were taken in from the hills on about the first of November until March so shepherds would not be on the hills watching over their sheep between these dates.

Addey[5], using the same evidence as Hughes[1] comes to a similar conclusion, that Christ was born in the Autumn of 7 BC. Using traditional astrology (apparently giving Christ's horoscope a strong Sun/Leo/fifth house element) and the early Christian tradition that Jesus was born on the day after the Jewish Sabbath, that is on a Sunday, Addey finds the characteristics of Jesus are best fitted by the horoscope for the evening of Saturday 22 August 7 BC (note that in the Jewish calendar the

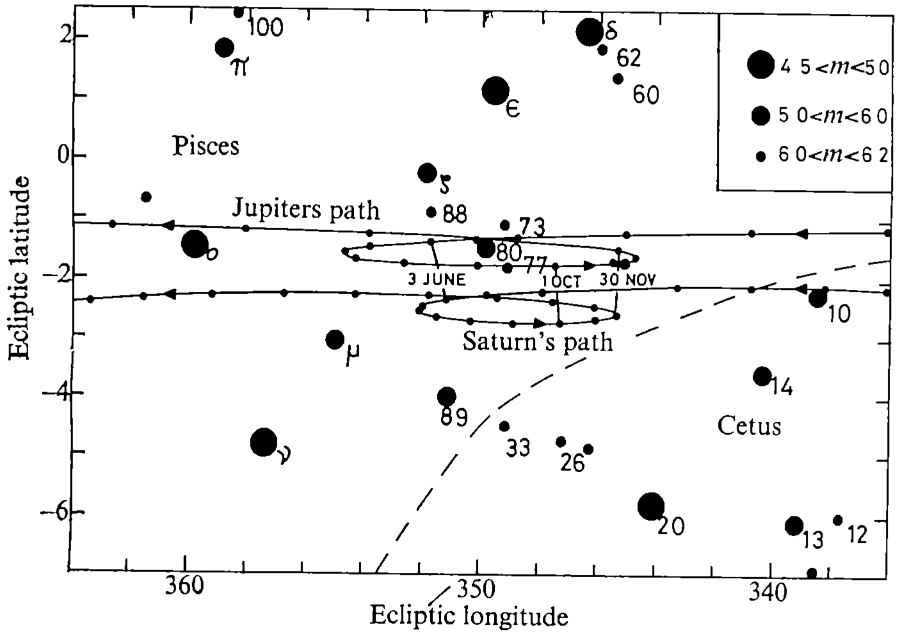

Fig. 2 The 7 BC triple conjunction of Saturn and Jupiter in Pisces. The ecliptic latitude and longitude have been taken from Tuckerman[2]. The dots on the planetary paths are separated by 20-day intervals; *m* is the apparent stellar magnitude.

day changes at sunset). The legend that Christ was born shortly after sunset, which originates from the Arabic Gospel of the Infancy, is also mentioned by Kestranek[6]. The mystical writings in The Urantia Book[7] give the time of Christ's birth as noon on 21 August 7 BC.

A novel hypothesis that has also been considered is that there were two Messiahs, both named Jesus born at slightly different times (ref. 8). Edwards supports this, pointing out that the nativity in Luke belongs as firmly to the reign of Archelaus as the Mathean nativity does to the reign of Herod the Great (O. Edwards, personal communication). Steiner[8] maintains that Matthew describes the birth of one Jesus, who was visited by the Maji whilst Luke describes the birth of a second Jesus who was born a little later and was visited by the shepherds and eventually crucified. The evidence he brings forward to support this claim is that Matthew and Luke give different genealogies, in Matthew Jesus being descendant from Solomon whilst in Luke He is traced back to Nathan. Second, in Matthew Jesus is born in a house and is visited by wise men, in Luke He is born in a stable and visited by shepherds. Third, Matthew describes the slaughter of the innocents and the flight into Egypt whilst this is not mentioned at all in Luke. This plurality of Messiahs was apparently concealed by Jerome and the newly official Church of the Roman Empire when they juggled with the different genealogies and expurgated the Infancy Gospels to produce a simple creed for the masses on whom the Church of the Roman Empire had been newly imposed. The expectation of the coming of two Messiah was often mentioned in the Dead Sea Scrolls found at Qumran in 1947.

Montefiore[9] considers another important point from ancient Jewish tradition. The Messiah–Haggadah[10] discusses the heptad in which the Son of David will come and states that in the fifth year "the Star shall shine forth from the East and this is the Star of the Messiah . . . and at the close of the seventh the Messiah is to be expected". This and other statements in the Midrashim in Jellenek's collection[11] indicate that a Star in the East was to appear two years before the birth of the Messiah. This ties in rather interestingly with Matthew II, 16 "Then Herod, when he saw that he was mocked of the wise men, was exceeding wrath and sent forth, and slew all the children that were in Bethlehem, and in all the coasts thereof, from 2 years old and under, according to the time which he had diligently enquired of the wise men". This "time" was obviously not the time of Christ's birth, which the Magi did not know when they first visited Herod, but was the time of the first appearance of the star. Using the triple conjunction hypothesis this occurred on 29 May 7 BC. Taking the old tradition that this would occur 2 years before the birth of the Messiah, Herod concluded that Jesus could have been born at any time between 29 May 7 BC and 29 May 5 BC and killed all the children of 2 years and under to be on the safe side.

Palmer[11] is perfectly correct in stating that the Magi could (like Lawrence of Arabia) have travelled from Babylonia to Jerusalem in 10 to 14 days and this must be taken as the lower limit for the journey time. The four months' journey time was mentioned in ref. 1 because this was the time taken by the Israelites when they were lead across the desert by Jehova on their return from captivity in Babylon. There is also a strong possibility that the Magi did not travel directly across the desert but took the easier but more distant route around the fertile crescent (Babylon, Mari, Carchemish, Ugarit, Byblos, Jerusalem—see Keller[12]).

Finally, a philological point[13]. Matthew uses the word star (αστηρ) four times (Matthew II, 2, 7, 9, 10) and each time it is used in the singular. Now αστηρ is not a word that is spelt the same way in both its singular and plural forms (the plural is αστερες), nor is it a collective noun (αστρον being a constellation), so it should not have been used to refer to more than one star. Second, if the 'star' of Bethlehem was a conjunction of two planets why didn't Matthew refer to 'planets' (πλανης αστηρ, a wandering star) and not stars? In answering these two points it must be remembered that Matthew's native language was not Greek, and also that Greek of the New Testament is not the classical Greek but the κοινη or popular everyday Greek, so words might not have been used in their strictly classical sense. Also Matthew, like other New Testament authors adhered in style and usage to the language of the Old Testament. 'Star' appears 24 times in the Old Testament, the word planet not appearing at all. So Matthew might just have used the better known expression.

The Matthean use of the singular was thought by Gerhardt[14] to refer simply to one planet in 7 BC, Saturn, the planet that was in conjunction with Jupiter. Saturn was "the protector of the Jews and reigned over their religion"—it was thus their star and the symbol of their Messiah.

Sodium and chloride in rainwater

PATERSON and Scorer[1] have suggested that methods used in rainwater analysis for Na^+ and Cl^- may give incorrect results and the increase in Na/Cl ratio reported by Hutton and Leslie[2] for inland samples collected in Victoria (Australia) relative to coastal samples may be an artefact. These suggestions are not acceptable.

Contamination of rainwater samples by Na is always possible and must be prevented as far as is practicable. In some Victorian samples Na was recorded at 0.2 μmol per 10^{-4} m^3 with the limit of detection being 0.1 and thus Na contamination should not be significant in samples reported as having 2 μmol per 10^{-4} m^3 or more. The limit of detection of Cl was 0.5 μmol per 10^{-4} m^3 and this limit imposes an artificial restriction on the Na/Cl ratio in dilute samples. Seawater with a Na/Cl ionic ratio of 0.858 when diluted to a Cl concentration of 3 μmol per 10^{-4} m^3 will have a ratio of 1 due to rounding to the nearest whole number and the value of R_s of 1.8 expected by Paterson and Scorer[1] will not be observed in at least 12 of the Victorian samples in their Fig. 3, it will be 1.5.

Nevertheless, there is enough evidence in the Victorian data to conclude that terrestrial sources contribute significant Na particularly at inland stations in summer and autumn. Hutton and Leslie[2] in their Fig. 3 show seasonal variations at six stations from coast to 320 km inland and in 14 out of the 17 sets of data the Na/Cl ratio in autumn is equal to or greater than the ratio in winter and in 9 out of the 11 sets of data the ratio in spring is equal to or less than the ratio in summer. Furthermore, the data in Table 1 give the following regression for 1955

$$\mathrm{Na/Cl} = 0.89 + 0.0022 \times d$$

($r^2 = 0.529$, $n = 24$) and for 1956

$$\mathrm{Na/Cl} = 0.86 + 0.0008 \times d$$

($r^2 = 0.454$, $n = 8$). (d = distance (km) from ocean in south-west direction). In both years at zero distance the value of the Na/Cl ratio is close to 0.86, the seawater ratio, and that in 1956, the wetter year for places usually receiving less than 625 mm of rain, the ratio changes less with distance.

It may be that the Eskdalemuir and Lerwick data (Fig. 2 in ref. 1) are not in error and the Wraymires site may be influenced by abnormal local factors.

J. T. HUTTON

CSIRO Division of Soils,
Glen Osmond, South Australia

[1] Paterson, M. P. & Scorer, R. S. *Nature* **254,** 491–495 (1975).

[2] Hutton, J. T. & Leslie, T. I. *Aust. J. Agric. Res.* **9,** 492–507 (1958).

PATERSON REPLIES—Hutton has missed the point of our discussion[1] of the published data on ionic ratios of sodium and chloride in precipitation. Our analysis of data from a number of studies, most of them connected with the European Air Chemistry Network, found that current theories on segregation of these elements after originating in sea salt aerosol, were based on uncorroborated data. When independent results allowed consistency to be checked, no support was found for any real deviation from the seawater ratio of Cl/Na which is 1.80 by weight. If chlorine in some form is driven off the sea salt through chemical or photochemical action, it seems to be brought back again in any cloud droplets which form on the aerosol, as would be expected from the high solubility of the Cl_2 or HCl which are the postulated gaseous forms. The Australian data of Hutton and Leslie[2] was introduced into the discussion because their finding of a deviation from the sea salt ratio, which may be an important result as it has been found in the rather different environment of the dry and clear Australian atmosphere, also requires corroboration by an independent system of sample collection and analysis. Hutton's continuing failure to come to grips with this consideration is indicated by his final statement, made without supporting argument, that "the Eskdalemuir and Lerwick data (in ref. 1) (may not be) in error and the Wraymires site may be influenced by abnormal local factors."

Hutton's claim (refs 2, 3) that much of the sodium and chloride in inland samples arises from terrestrial sources is supported by a considerable weight of evidence, including the reanalysis of Hutton's Mildura data[4] by Paterson[5] which indicates that both elements are collected by that rain gauge at a rate which is effectively independent of the amount of rain during the month. This suggests that much of it has arrived as a dry deposit of aerosol, in quantities substantially greater than those found at a similar distance inland in Europe and North America. The range of atmospheric transport of these particles remains an open question, especially in view of Bigg's observation (personal communication) that extensive sampling from aircraft over wide areas of inland Australia has revealed very low concentrations of particles from any natural source. Perhaps the explanation is to be found in Dulhunty's observation[6] of the intermittent but intense dry storms which raise material from the dry salt lakes in brief episodes. Galbally (personal communication) has reported sightings from the air of 'salt devils' raised by willy willies crossing the dry lake beds.

Habitat values and endemicity in the vanishing rain forests of Sri Lanka

In our paper[1] the following scientific names were misspelled due to proof reading by committee. The correct spellings are *Nannophrys guentheri, Ramanella obscura, Cophotis ceylanica, Lyriocephalus scutatus, Otocryptis wiegmanni, Geckoella triedrus, S. taprobanensis, S. diegnani, Nessia burtoni* and *A. hickanala.*

Table 2 in the same paper was based on inaccurate estimates of the areas of the Regions. Our figures were obtained from the Department of Agriculture of Sri Lanka and were too large by a factor of about 1.4. We have prepared a more accurate rendition of the table using the areas in Kahawita[2] (Table 1), but since the ratios of the areas of the four regions are hardly affected the ratios of the habitat values and our conclusions are conserved.

We thank Dr H. Crusz at the Department of Zoology, University of Sri Lanka, Peradeniya, Sri Lanka, for pointing out the errors.

Physical space and time

D. J. Raine

Space and Time in the Modern Universe. By P. C. W. Davies. Pp. viii+232. (Cambridge University: Cambridge, London and New York, 1977.) Hardback £6.50; paperback £2.95.

THERE was a time when the sins of the world would be explained through Quantum Theory and excused by Relativity. But the relevance of science to society is not so crude, and in due course Heisenberg and Einstein and their friends were returned to Academe. Nor is the relevance of science to be measured solely in terms of the subsequent military and technological applications, for the General Theory of Relativity at least—in some contrast to the Special Theory—has as yet no such applicability. This much it shares with the Copernican theory. That new vision has not changed one bit the motion of the Sun, or helped us to burn its light. Yet, as the contemporary Church understood well that it would, in shaping the way we see ourselves in relation to the World, the Copernican view has influenced our lives more than any display of military genius or noble act of statesmanship. And General Relativity, as part of our newly forming picture of the space time of the Universe may yet prove to have a similar relevance.

In *Space and Time in the Modern Universe,* Dr Davies is concerned to communicate, in a basically non-mathematical form, the status of our present understanding of physical space and time. He takes the reader from the mathematical idea of the continuum through Newtonian mechanics to electromagnetic theory and the space time of Special Relativity; from Newtonian gravity to the space time of General Relativity; from the microscopic world of the quantum to the Universe as a whole. Among the unresolved problems to which we are introduced are the reconciliation of the time symmetry of physical laws and the time asymmetry of natural processes; the reconciliation of Quantum Theory and General Relativity, still far from understood despite the progress which has been made in the quantum mechanics of black holes; and the reconciliation of the successes of General Relativity with the fact that it seems, in the singularity theorems, to predict its own inadequacy.

To encompass this vast range, Dr Davies adopts what one might call the synoptic approach. The danger of this style is the ease with which it becomes a mere recital of the table of contents of the book of physical thought. So wide-ranging is the discussion that the author's skill in making a point with a deftly chosen analogy or a succinct diagram does not always enable him to escape this pitfall. Thus, quasars are no more than "strange objects", spontaneous emission is not stimulated as in lasers, and escape velocity is *"escape velocity"*.

In selecting concepts for further discussion—and clearly considerable selection is required—there is a wide variation in the demands made on the reader. For example, he is expected to understand that higher frequency photons have higher energies (mentioned in passing in a discussion of radiation pressure); or consider ". . . the presence of electrically conducting materials will modify the fluctuations of photons ('particles' of electromagnetic radiation)" which, albeit for the second time, contains the only definition of photons given and for which more than a passing acquaintance with physics is required. On the other hand, the book starts by distinguishing between space and "outer space"; great care is taken to explain that the Solar System consists of the Sun and nine planets; and can anyone who does not already know what an element is, be expected to find it clear that a hot gas emits X rays?

These might be thought to be minor blemishes from which not even a masterpiece would be entirely free. I feel, however, that they are more likely to be symptomatic of an underlying unresolved pedagogic problem. For example, if it is emphasised that Special Relativity is a macroscopic theory which does not apply in the atomic domain, how is anyone without a high degree of physical maturity to understand that it is by incorporating this same relativity into the atomic description that Dirac discovered anti-matter? And compare the beautiful construction and dramatic effect of the chapter on time asymmetry with the visible discomfort at the need to explain the 'extraordinary' Quantum Theory *ab initio* in a few pages—and the almost audible sigh of relief on returning to relativity.

To be fair, it is indeed clearly stated that the book is addressed to those who already know enough of the subject to have asked themselves what might happen before the 'big bang' or at the centre of a black hole. Yet in the writing of the book, it seems that at times Dr Davies must have felt he might reach a wider audience. Certainly the results are of such importance that one can understand the desire to communicate them beyond the undergraduate physicist. But the problems are so difficult that it is probably impossible to satisfy entirely the whole of this wider audience in a single book.

In the final chapter of the book, Dr Davies turns to Man and the Universe. Here what matters is not so much the details of what has gone before but rather that it provides a reasonably coherent view of a Universe evolving. If the Universe is infinite and if the probability of the emergence of life is greater than zero, then there are infinitely many beginnings to Civilisation. It may be the destiny of some of these to evolve, to understand and perhaps to control their World. We are too young to know. If only a physicist would claim that the physical basis of life is now understood—and if Dr Davies is too optimistic in claiming that we already understand the evolution of structure in the Universe—nevertheless, such an understanding certainly seems to be emerging. And if we look outwards from ourselves to view this new Universe, this puts a unique complexion on our lives. What is important is that as many people as possible should be brought to know this view. □

D. J. Raine is Lecturer in Theoretical Astrophysics in the Department of Astronomy at the University of Leicester, UK.

Intermediate astronomy

Astronomy: Principles and Practice. Pp. 341. *Astronomy: Structure of the Universe.* Pp. 283. By A. E. Roy and D. Clarke. (Adam Hilger: Bristol, UK, 1977.) Hardback £10; paperback £7.50 each volume.

ASTRONOMY owes its educational value to a combination of separate factors: historical and literary associations, a wealth of comparatively easily understood applications of the scientific method, an increasingly significant relationship with the environment as revealed by modern space research, and its fundamental role in exploring what sort of Universe we live in. As Plato said, astronomy is good for the soul, and increasing recognition of this fact has led in recent years to the production of a large number of lively and beautifully illustrated books directed at 'liberal arts' students and bright youngsters, often making little or no use of formal mathematics; a few of these have been reviewed in *Nature* (**266**, 102, 3 March, 1977) by D. W. Hughes. For those with the mathematical equipment of a first-year honours student in physical sciences, an admirable compact survey of the whole field is provided by A. Unsöld's *New Cosmos* (of which an English version of the second edition is currently in press), whereas numerous other books deal with particular aspects in more detail.

The present two volumes by Roy and Clarke aim at an intermediate level. They are based on university and extramural lectures given by the authors at Glasgow over a number of years, and contain essentially the material of the first-year university course attended by beginning science students (who study a range of subjects at this stage) and a minority of arts students wishing to gain some knowledge of the workings of science and the scientific method. The first volume, beginning with naked-eye phenomena and a brief description of the observables, proceeds in classic Glaswegian tradition to give a thorough grounding in elementary spherical trigonometry, positional astronomy and celestial mechanics, including useful topical references to Megalithic observatories and space-probe orbits. A short introduction to atomic and radiation physics leads on to the second major section discussing optics, optical and radio telescopes, detectors and instruments, with a final chapter describing a number of practical projects, mostly concerned with positional astronomy but with some optics and spectroscopy as well, that involve very simple equipment. The second volume describes the objects and phenomena of astronomical research: members of the Solar System, tides and eclipses, stellar magnitudes, colours and spectroscopy, variable and binary stars, stellar atmospheres, interiors and evolution, stellar motions, nebulae, galactic structure, galaxies, cosmology, cosmogony and the question of extraterrestrial life.

Admirably illustrated and neatly packaged into 40 separate chapters with exercises, the two volumes are very successful in giving a clear exposition and in driving points home. The treatment and content, however, are not very well adapted to the needs of either honours students or liberal arts students, nor to those of bright youngsters. The mathematical approach is distinctly old-fashioned, with spherical triangles solved in remorseless detail (including logarithms of cosines written out in full), celestial mechanics without benefit of vector analysis, and trivial relationships involving stellar magnitudes spelled out at length.

The scope of the second volume is severely limited: to take just two examples, there is no mention of curves of growth or opacity in stellar atmospheres, and in the section on cosmology, General Relativity is merely mentioned as satisfying the classical observational tests without any account of the Principle of Equivalence or of any other idea connected with it, so that the notion of the curvature of space then comes right out of the blue. Thus the present book gives considerably less information on astrophysical topics than does the largely non-mathematical treatment of the entire field by G. O. Abell in *Exploration of the Universe*. The practical outlook, and the clarity and thoroughness of treatment (up to the chosen level) of those topics that have been selected for coverage, will, however, make this book a useful work of reference, especially for ambitious amateurs and for teachers of extramural courses.

Bernard Pagel

Bernard Pagel is Deputy Chief Scientific Officer at the Royal Greenwich Observatory, and Visiting Professor at the Astronomy Centre, University of Sussex, UK.

Viruses and cell surface changes

Cell Surface Reviews. Volume 2: Virus Infection and the Cell Surface. Edited by G. Poste and G. L. Nicolson. Pp. 342. (North-Holland: Amsterdam, New York and Oxford, 1977.) $55.95; Dfl.137.

THE nature of surface changes induced by interactions between viruses and cell membranes is currently a topic of considerable interest to many virologists and cellular immunologists. This follows the realisation that cell-mediated immunity in virus diseases reflects surface monitoring of virally modified cells by re-circulating thymus-derived lymphocytes (T cells). Both viral and host components are apparently involved in T cell recognition. The evidence that has led to this concept is reviewed here by Blanden, Pang and Dunlop, and Burns and Allison. The area is, however, moving quickly and this volume is rather tardy, so some of the ideas expressed now have little currency.

The subject has not always been so fashionable. In fact, most of the virologists writing for this book are either unaware of, or have chosen to ignore, the trendy speculations of the cellular immunologists. This is somewhat of a relief. The result is a series of detailed reviews of established knowledge in areas that seem, in the main, to be relatively stable. The topics covered range through interactions of viruses with tissues (Smith, Weiner and Johnson), nucleated cells (Hosaka and Shimizu, Burns and Allison), erythrocytes (Bächi, Deas, and Howe) and model membrane systems (Tiffany). A thorough account of the structure and assembly of viral envelopes is provided by Rott and Klenk. Those considering the problem of immunological recognition of virally modified cells may benefit considerably from exposure to this information.

If I were to recommend, however, that a library acquire this very expensive volume, it is the article by Lindenmann that would induce me to do so. Lindenmann considers the various steps that led to general acceptance of the idea that a host-coded component, a carbohydrate moiety, is incorporated in budding influenza viruses. He uses this as a format to discuss both how science is done, and how credit is given (or denied) for what is done. The article is extremely readable, being written with some humour and considerable insight. This is recommended reading for students of virology, immunology and of the philosophy of science.

The book is well produced. Unfortunately, it has one major defect for those of us who read everything backwards. Individual articles are only identified at the beginning of each chapter. Printing of the authors names and/or a short title at the top of facing pages would make future volumes much more accessible for rapid reference.

P. C. Doherty is Associate Professor at the Wistar Institute of Anatomy and Biology, Philadelphia, Pennsylvania.

Mammalian cell membranes

Mammalian Cell Membranes. Vol. 4: Membranes and Cellular Functions. Pp. 262. Vol. 5: Responses of Plasma Membranes. Pp. 260. Edited by G. A. Jamieson and D. M. Robinson. (Butterworths: London and Boston, Massachusetts, 1977.) £18 each volume.

WITH these books, Jamieson and Robinson close the circle of their edited series on the structure and function of mammalian cell membranes. Volume 4 is concerned with ultrastructural, biochemical and physiological aspects. In the first chapter Deamer provides a brief account of freeze-etch images and an interpretation of intramembraneous particles. This is a useful companion to later discussions of the permeability of membranes by De Pont and Bonting, and of membrane action potentials by Carpenter.

The bulk of Volume 4 is concerned with functional aspects of cell surface membranes and receptor theory. The antigenicity of cell surfaces is well covered by Weiss and Klavins—in particular, the section on the structural relationships between CEA and blood group substances—although I was startled to see references to Feizi *et al.* (1900) on pp. 74 and 95 in view of the sensationally youthful appearance of Dr Ten Feizi of the Northwick Park Clinical Research Centre.

Surface immunoglobulins and the controversy of the T-cell receptor are dealt with admirably by Kern, and Edwards provides a succinct account of current thinking in cell adhesion. Ashwell summarises the present belief of many concerning the role of surface carbohydrates in recognition phenomena, including some of those appearing in Edwards' chapter. In addition to describing briefly his own classical experiments, Ashwell reminds us of the pioneering and still provocative work of the Gasics in the related area of cell surface carbohydrates and host responses to tumours.

Volume 5 is concerned with the way in which the external environment affects the cell surface membrane, and *vice versa.* The environment in the most fundamental sense includes the effects of hydrostatic pressure (Zimmerman and Zimmerman), water structure (Meryman) and radiations (Patrick) on membranes. At the other extreme of specificity, Birnbaumer *et al.* make interesting sense of the huge literature on receptor coupling with adenyl cyclase, and on the regulation of the coupling by nucleotides. Strangely enough, the action of cholera toxin on membranes is not mentioned as a 'model' of hormone interactions with target cells.

In many biological processes, remodelling of cell surface membranes must occur. Several examples are considered in this volume, including endocytosis by Stockem, membrane fusion by Barski, membrane changes accompanying normal cell growth by Knox and Pasternak, and the senescent process by Robert. The best characterised of all remodelling processes, accompanying viral infection, is excellently treated by Klenk. The basic mechanisms by which membrane remodelling occurs is still a matter of speculation, although Scanlin and Glick clearly define the biochemical principles and dynamic nature of membrane turnover and discuss the concept of membrane flow.

I have now had the opportunity to read or browse through all five books of the series on *Mammalian Cell Membranes* and no doubt shall continue to profit from the immense amount of information therein for many years. The editors are to be congratulated on the success of their project, and they and their colleagues deserve our gratitude for providing a solid platform from which to view the rapidly changing membrane scene.

Strange compendium

Handbook of Unusual Natural Phenomena. By William R. Corliss. Pp. 542. (The Sourcebook Project; Glen Arm, Maryland, 1977.) $14.95.

WILLIAM CORLISS has been producing his 'sourcebooks' of such strange phenomena as ball lightning, plagues of frogs and miscellaneous phenomena associated with earthquakes since 1974. In the past, these have taken the form of loose-leaf folders containing synoptical accounts of observations reported in a wide variety of journals (with *Nature* prominent among them) and over a long period (back into the nineteenth century). The present 'handbook' presents the mixture as before but in more substantial and permanent form, as a bound volume of more than 500 pages, full of fascinating morsels.

The entries range in length from a couple of lines to a page or more plus diagrams, and cover in this volume phenomena grouped together as luminous phenomena, optical and radio anomalies, unusual weather phenomena, mysterious natural sounds, strange phenomena of earthquakes, phenomena of the hydrosphere and falling material. For anyone suffering from the delusion that science has reached a comforting state of explaining just about everything, the book may provide a few shocks; for the less sanguine among us, here is a delightful source of bed-time reading, full of anecdotes with which to amaze and amuse colleagues the next day. And, who knows, by reviving interest in such curiosities as the shower of sand eels reported by A. Meek in *Nature* (**102,** 46; 1918), Corliss may well encourage the development of an improved scientific understanding of some unusual natural phenomena.

Beat the machine

Advances in Computer Chess. Edited by M. R. B. Clarke. Pp. 118. (Edinburgh University: Edinburgh, 1977.) £3.50.

IT is now many years since the electronic computer greatly exceeded the human brain in terms of speed and accuracy in calculation. But even in applications to well defined, finite games, such as chess, where this quality is at a premium, computers cannot match the performance of the more able human players.

This human advantage can largely be attributed to the possession of an ill-defined capability known as 'common sense', a concept unknown to computers. In the situation of the chess game, its activities are manifested in the human's ability to reject most of the moves available to him as unworthy of analysis, and to analyse only those which are 'sensible'.

This book, consisting of a set of articles from a symposium held in Oxford in 1975, deals with the problem of programming 'common sense' into a computer. In the chess context, this amounts principally to techniques of search reduction at the tactical level, and rudimentary 'planning' at the strategic level. A short article on the mathematical theory of search techniques, and several examples of the success (or lack of it) of practical programmes, complete a collection which should be worthwhile reading for those interested in the problems of machine intelligence.

N. J. Holloway is Lecturer in the Astronomy Centre at the University of Sussex, UK.

Narrow gap semiconductors

Semimetals and Narrow-Bandgap Semiconductors. By D. R. Lovett. Pp. viii+256. (Pion: London, 1977.) £8.50; $17.50.

AT FIRST GLANCE this book has a pleasing appearance with many clear diagrams and graphs, and a more detailed examination has convinced me that the breadth and depth of coverage should make it a very useful book for those entering the field of electrical properties and applications of narrow gap semiconductors.

The book is basically in two parts. In the first part, there is an excellent and concise introduction to phase diagrams and crystal growing techniques, clearly outlining the many pitfalls and problems which would confront anyone trying to prepare pure and homogeneous materials. The chapter on crystal symmetry and band properties is probably the weakest part of the book, for it is so concise as to be practically of no help to anyone except those already initiated in the art. The electrical properties is well treated and is somewhat similar to Putley's well-known book *Hall Effect and Related Phenomena.* There is also a chapter briefly reviewing narrow band gap devices.

The real interest of the author is expressed in the second half of the book, dealing with the much more detailed aspects of particular materials, ranging from bismuth–antimony alloys to selenides, tellurides and arsenides. This latter part of the book would certainly be of very considerable use as a source of information for both the researcher as well as those interested in the application of narrow band semiconductors.

At £8.50 this book is certainly value for money for those on the periphery of this field.

Analysing pure substances

Spectrochemical Analysis of Pure Substances. Edited by Kh. I. Zil' berstein. Translated by J. H. Dixon. Pp. 435. (Plenum: London and New York, 1977) £27.

THIS English translation of the (1971) Russian edition, stated by the publishers to be thoroughly revised and up-to-date, contains 1,497 references, over half to Russian work, but less than ten after 1971. A vast amount of information on trace analysis is given, most of it in an uncritical review form of Russian and Eastern European work.

In Part I, the first three chapters give excellent, but over-lengthy and unbalanced, sections on evaluating limits of detection, and their improvement by optimising parameters of spectral resolution. Reference to spectrographic equipment by symbol only would have been of more value if a table had been given listing their main features such as focal length. In chapter 4 a long description is given of arc sources which, although biased towards Russian work, describes in detail the various distribution parameters across electrode gaps of d. c. and a. c. arcs, with anode and cathode excitation, and the resulting line-to-background ratios. Techniques for introducing samples into the arc are reviewed and methods of stabilisation, such as the use of external magnetic fields and various forms of constricted arcs are discussed. Other sources are covered in less detail, but the glow discharge is noticeably absent.

Part 2 describes preliminary concentration methods, starting with a rather cumbersome mathematical section on the expression of the concentration factor, followed by more useful sections on concentration by volatilisation, sublimation, crystallisation, zone melting, solvent extraction, ion exchange, coprecipitation and electrodeposition.

Part 3 deals with practical problems including sampling, grinding, laboratory design, purification of reagents and carbon electrodes, and more briefly with the preparation of synthetic standards. The final section, on practical methods of analysing pure substances, is a ten-page list of sample types, noting the trace elements determined, and giving references in the bibliography.

The contents of the book and its translation are excellent. It is full of valuable information, but this can only be found by thorough study, as the index is totally inadequate. I can foresee two types of reader: the spectroscopist, who may obtain some new lines and those who wish to be made aware of Eastern-European work. Both would be justified in purchasing this book. Readers should note, however, that some of the Russian claims to priority are unjustified according to the record of world literature.

T. S. West is Director of The Macaulay Institute for Soil Research, Aberdeen, Scotland, UK, and formerly Professor of Analytical Chemistry, Imperial College of Science and Technology, University of London, UK.

Endocrinology yearbook

The Year in Endocrinology, 1975–1976. Edited by Sidney H. Ingbar. Pp. xviii+327. (Plenum Medical: New York and London, 1976.) $27.

'YEARBOOKS' come in many shapes and sizes. Probably the commonest format is the upgraded textbook in which a series of chapters, whose headings embrace non-selectively the whole of the subject under consideration, seek to convey to the reader the principal advances which have taken place since the previous edition. Often, each chapter will consist of summaries of key papers accompanied by editorial comment. The contrary approach is the presentation of a series of highly selective reviews by eminent authorities, usually with a heavy bias towards the work of their own groups. The present volume falls somewhere between the two. Nine chapters by individual authors review the principal endocrine systems except those of the foeto-placental unit and the gut. Most are comprehensive, but there are occasional notable exclusions: for example, the section on neuroendocrinology makes no mention of the posterior pituitary gland, whereas another concentrates on calcitonin and ignores parathyroid hormone. Finally, there are two special essays on ectopic hormone secretion and the mechanisms of steroid hormone action.

The general standard of the individual chapters is high and as a review of the state of the art for readers in 1977 there is no doubt that this is a useful book. The transatlantic flavour, however, is noticeable by the absence of comment on important therapeutic advances. For example, the use of ergot derivatives in the treatment of hyperprolactinaemia is dimissed in a few lines and a single minor reference. This is surprising since the use of Bromocriptine is probably the single most important development in endocrine management of the 1970s, and the bulk of the significant papers on this subject appeared in the time period in which this book purports to cover. Far more space is devoted to the use of the gonadotrophin-releasing hormone, despite the fact that it is unlikely this material will ever be of great practical value. These comments apart, the book can be commended to the practising endocrinologist.

announcements

On the Move

R. S. Barnes, Chief Scientist of the British Steel Corporation since 1975, and previously its Director of Research and Development, to Principal of Queen Elizabeth College, London University, on 1 April 1978.

K. G. Adiyodi, Profesor of Reproductive Physiology, Calicut University, India and Secretary, International Society for Invertebrate Reproduction, to Department of Zoology, Oxford University, South Parks Road, Oxford.

C. D. Bridges, Professor of Experimental Ophthalmology at New York University Medical Center, to Professor of Ophthalmology at the Baylor College of Medicine, Houston, Texas.

Professor Y. K. Levine from Department of Physical Chemistry, University of Leeds, to the Chair of Biophysics at the University of Utrecht.

Details of changes of department, sabbaticals, where leave will be taken and so on should be sent to On the Move; there is no charge for this service.

Appointments

Sir Ieuan Maddock, previously Chief Scientist at the Department of Industry, is to succeed Magnus Pyke as Secretary of the British Association for the Advancement of Science on 7 September 1977.

R. Frosch, previously a director of the Woods Hole Oceanographic Institution, to Head of NASA.

A. J. Lee, Director of Fisheries Research at Lowestoft for the Ministry of Agriculture, Fisheries and Food, to Controller of Fisheries Research and Development for Great Britain.

J. Black, Professor of Pharmacology at University College, London, is to join the Wellcome Research Laboratories at Beckenham, Kent, as Director of Therapeutic Research. He will lead the search for new chemical compounds and their testing for activity and safety with the aim of finding new medicines for the control of the functions of the body. He expects to be working at Beckenham full-time by 1 January, 1978.

A. C. Fabian to the newly-established Radcliffe Fellowship in Astronomy, to be based at the Cambridge Institute of Astronomy where his research will concentrate on X-ray astronomy and related optical studies.

W. D. M. Paton, Professor of Pharmacology at the University of Oxford is to succeed Sir J. McMichael as a trustee of the Wellcome Trust from 1 January 1978.

Awards

Dr J. E. Castle is the recipient of the Beilby Medal and Prize for 1977, the joint award of the Royal Institute of Chemistry, the Society of Chemical Industry and the Metals Society, for his work on the chemistry and metallurgy of surfaces, particularly studies of metallic corrosion by photoelectron spectroscopy.

Person to Person

Exchange furnished house in Richmond, Virginia, for similar in Cambridge, England from January 1978 to January 1979. Car exchange also. Contact Judith Bond, Department of Biochemistry, Medical College of Virginia, Virginia Commonwealth University, Richmond, Virginia 23298, USA.

Exchange 2-bedroom apartment in Jerusalem for similar in Bethesda area, Maryland, for one year beginning September/October 1977. Contact D. BenEzra, National Institutes of Health, Bldg 10, Room 10D-09, Bethesda, Maryland 20014, USA.

There will be no charge for this service. Send items (not more than 60 words) to Marcus Dobbs at the London office. The section will include exchanges of accommodation, personal announcements and scientific queries. We reserve the right to decline material submitted. No commercial transactions.

Meetings

12–14 September, **Conference on Scanning and Transmission Electron Microscopy,** Glasgow, UK (Institute of Physics, 47 Belgrave Square, London SW1, UK).

11–17 September, **VIth European Congress of Pathology,** London, UK (Conference Services Ltd, 43 Charles Street, London W1, UK).

13–15 September, **Particle Size Analysis Conference,** Salford, UK (D. Dollimore, Reader in Physical Chemistry, University of Salford, Salford, UK).

12–16 September, **3rd International Conference on Bioindicators and Landscape Deterioration,** near Prague, Czechoslovakia (Ustav krajinné ekologie CSAV (Ing. J. Spáleny CSc.) 252 43 Pruhonice, Czechoslovakia).

26–27 September, **Conference on Dynamic Small European Companies in the Health-Care Industry, and Why they are Successful,** Brussels (Robert S. First, Inc., Avenue Marnix, 19A, 1050 Brussels, Belgium).

12–14 October, **Working Group on Rehabilitation and Secondary Prevention in Patients with Acute Myocardial Infarction,** Valencia (WHO, Regional Office for Europe, 8 Schefigsvej, DK-2100 Copenhagen, Denmark).

11–13 August, **Annual Meeting of the American Society of Pharmacognosy,** Washington (L.R. Brady, Pharmacy, University of Washington, Seattle, Washington 98195.

1–2 September, **The 571st Meeting of The Biochemical Society,** Dublin (Meetings Officer, The Biochemical Society, 7 Warwick Court, London, UK).

4–8 September, **3rd International Conference on Microprobe Analysis in Biology and Medicine,** Munster, West Germany (P. Echlin, Department of Botany, University of Cambridge, Cambridge, UK).

5–9 September, **European Conference on Precise Electrical Measurement,** Brighton (Institute of Electrical Engineers, Savoy Place, London, UK).

6–9 September, **7th European Microwave Conference and Microwave 1977,** Copenhagen (MEPL, Temple House, 34–36 High Street, Sevenoaks, Kent, UK).

6–9 September, **Conference on Digital Processing of Signals in Communications,** Loughborough (Conference Secretariat, Institution of Electronic and Radio Engineers, 8–9 Bedford Square, London, UK).

6–8 September, **Conference on Scaling for Performance Prediction in Rotodynamic Machines,** London (The Institution of Mechanical Engineers, 1 Birdcage Walk, London, UK).

8 September, **Seminar on Corrosion and Fatigue in Offshore Installations,** London (The Institution of Mechanical Engineers, 1 Birdcage Walk, London, UK).

12–15 September, **7th European Conference on Solid State Devices Research,** Brighton (Meetings Officer, Institute of Physics, 47 Belgrave Square, London, UK).

8 September, **The Draughting and Preparation of an Iso Standard on Nuclear Quality Assurance,** London (The Institution of Mechanical Engineers, 1 Birdcage Walk, London, UK).

13 September, **Mini-Computers—Applications,** London (The Institution of Mechanical Engineers, 1 Birdcage Walk, London, UK).

13–15 September, **Conference on Heat and Fluid Flow in Water Reactor Safety,** London (The Institution of Mechanical Engineers, 1 Birdcage Walk, London, UK).

14–16 September, **3rd European Conference on Optical Fibre Communication,** Munich (W. Harth, Lehrstuhl f. Allg. Elektrotechnik der Technischen Universiät München, Arcisstrasse 21, D-8000 Munich 2, Germany).

14–16 September, **3rd National Conference on Quantum Physics,** Southampton (Meetings Officer, The Institute of Physics, 47 Belgrave Square, London, UK).

15 September, **Pressure Vessel Codes—Change and Advance,** London (The Institution of Mechanical Engineers, 1 Birdcage Walk, London, UK).

15–16 September, **Conference of the Schizophrenia Association of Great Britain,** London (Hon. Secretary, Tyr Twr, Llanfair Hall, Caernarvon, Wales).

Reports and Publications

UK & Ireland—June

Residential Short-term Care for Mentally Handicapped People: Suggestions for Action. (Pamphlet No. 4.) Pp. v+9. (London: National Development Group for the Mentally Handicapped, Alexander Fleming House, SE1, 1977.) [16

Laboratory Practice Reviews of Current Techniques and Instrumentation. Edited by Bevan M. Gilpin. Pp. 82. (London: United Trade Press, Ltd., 42/43 Gerrard Street, W1, 1977.) £5. [16

British Pharmacopoeia 1973: Addendum 1977. (Published on the recommendation of the Medicines Commission pursuant to the Medicines Act 1968.) Pp. xix 72. (London: HMSO, 1977.) £6 net. [16

Analysis by Gas Chromatography: Foods and Beverages. Pp. 34. (Cambridge: Pye Unicam, Ltd., York Street, 1977.) [26

Ship and Marine Technology Requirements Board. Report 1976-77. Pp. 8. (London: SMTRB Secretariat, Department of Industry, Abell House, John Islip Street, SW1, 1977.) *gratis.* [26

Critical Evaluation of Some Equilibrium Constants Involving Alkylammonium Extractants. By A. S. Kertes. (International Union of Pure and Applied Chemistry: Analytical Chemistry Division.) Pp. v+30. (Oxford and New York: Pergamon Press, 1977.) £3.30. [36

CISHEC: Chemical Industry Safety and Health Organization—Guide. Pp. 16. (London: Chemical Industries Association, 93 Albert Embankment, SE1, 1977.) *gratis.* [36

University of Oxford. Ashmolean Museum—Report of the Visitors, 1975-1976. Pp. 72+18 plates. (Supplement No. 3 to the *University Gazette.*) (Oxford: The University, 1977.) £2.

Weed Research Organization. Technical Report No. 15: Methods of Analysis for Herbicide Residues. By T. H. Byast, E. G. Cotterill and R. J. Hance. Second edition. Pp. 58. (Oxford: ARC, Weed Research Organization, Begbroke Hill, Yarnton, 1977.) £5.75. [86

Philosophical Transactions of the Royal Society of London. B: Biological Sciences. Vol. 279, No. 964: Studies of the Blue Astaxanthin-Proteins of *Velella velella* (Coelenterata: Chondrophora). By P. F. Zagalsky and P. J. Herring. Pp. 289-326. UK £2.30; Overseas £2.40. Vol. 279, No. 965: A Quantitative Survey of the Biota of Intertidal Soft Substrata on Aldabra Atoll, Indian Ocean. By R. N. Hughes and J. C. Gamble. Pp. 327-355. UK £1.75; Overseas £1.80. (London: The Royal Society, 1977.) [86

University of Bristol: Department of Agriculture and Horticulture. Long Ashton Research Station: The National Fruit and Cider Institute—Report 1976. Pp. xvi+208. (Long Ashton, Bristol: Long Ashton Research Station, University of Bristol, 1977.) £2.25. [106

An Alternative Energy Strategy for the United Kingdom. Edited by Dr. R. W. Todd and Dr. C. J. N. Alty. Pp. 30. (Machynlleth, Powys: National Centre for lAternative Technology, 1977.) [136

Are The Lamps Going Out? By Sir Michael Swann. Pp. 15. (The 1977 Clayesmore Lecture, at Clayesmore School, Friday 4 March 1977.) (London: BBC, 1977.) [136

List of University Institutions in the Commonwealth, Twenty-first edition. Pp. 32. (London: The Association of Commonwealth Universities, 36 Gordon Square, WC1, 1977.) [136

Rothamsted Experimental Station. Rothamsted Nematology Department: Publications by past and present members and associated up to 1976. Pp. 150. (Harpenden: Rothamsted Experimental Station, 1976.) [146

The British Industrial Biological Research Association. Annual Report 1976. 58. (Carshalton, Surrey: BIBRA, 1977.) [156

Philosophical Transactions of the Royal Society of London. B: Biological Sciences. Vol. 279, No. 966: An Electron Microscopic Study of the Centre-Median and Ventrolateral Nuclei of the Thalamus in the Monkey. By B. N. Harding and T. P. S. Powell. Pp. 357-412+plates 1-35. UK £9.63; Overseas £9.88. Vol. 279, No. 967: Flow Behaviour of Blood Cells and Rigid Spheres in an Annular Vortex. By T. Karino and H. L. Goldsmith. Pp. 413-445+plate 1. UK £2.15; Overseas £2.25. Vol. 279, No. 968: On *Anthracosaurus russelli* Huxley (Amphibia : Labyrinthodontia) and the Family Anthracosauridae. By A. L. Panchen. Pp. 447-512+plates 1 and 2. UK £4.30; Overseas £4.45. (London: The Royal Society, 1977.) [156

Office of Population Censuses and Surveys. Local Authority Vital Statistics: Vital Statistics for Administrative and Health Areas of England and Wales, 1975. (Series VS, No. 2). Pp. viii+16. (London: HMSO, 1977.) 85p net. [166

Philosophical Transactions of the Royal Society of London. A: Mathematical and Physical Sciences. Vol. 285, No. 1329: Theory of Isomorphous Replacement in Aluminosilicates. By R. M. Barrer, F.R.S., and J. Klinowski. Pp. 637-680. UK £2.40; Overseas £2.50. Vol. 286, No. 1330: Observations of the Semidiurnal Internal Tide in the Western North Atlantic Ocean. By R. M. Hendry. Pp. 1-24. UK £1.45; Overseas £1.50. (London: The Royal Society, 1977.) [166

International Planned Parenthood Federation. Occasional Essays. No. 2: Population and National Development—The Dilemma of Developing Countries. By Fred T. Sai. Pp. 31. 85p; $1.50 plus postage. No. 3: Food, Population and Politics. By Fred T. Sai. Pp. 36. 85p; £1.45 plus postage. (London: International Planned Parenthood Federation, 18/20 Lower Regent Street, SW1, 1977.) [176

Report of The Rugby School Natural History Society for the year 1975-1976. Pp. 16. (109th Issue.) (Rugby: Rugby School Natural History Society, 1977.) [206

Units, Symbols, and Abbreviations: a Guide for Biological and Medical Editors and Authors. Edited by B. N. Baron. Pp. 48. (London: The Royal Society of Medicine, 1977.) £2. [206

International Institute for Environment and Development. IIED Energy Project. Energy Conservation in UK Dwellings: Domestic Sector Survey and Insulation. By Frederic Romig and Gerald Leach. Pp. 86. (London: IIED, 27 Mortimer Street, W1, 1977.) [206

Cranfield Institute of Technology. Annual Report for 1976. Pp. 24. (Cranfield, Bedford: Cranfield Institute of Technology, 1977.) [206

Land Use Studies by Remote Sensing. Edited by W. G. Collins and J. L. van Genderen. Pp. 164. (Remote Sensing Society.) (Birmingham: The Remote Sensing Unit, Department of Civil Engineering, University of Aston, Gosta Green, 1976.) [216

Department of the Environment. Department of Transport—Library Services. Annual List of Publications, 1976. Pp. vi+149. (South Ruislip: DOE/DTp Sub-Library, Bldg. 6, Victoria Road, 1977.) *gratis.* [216

Proceedings of the 1976 Canadian SRE Reliability Symposium, Saturday June 5, 1976. Colonel By Hall, Ottawa, Ontario, Canada. (*Microelectronics and Reliability*, Vol. 15, Supplement, 1976.) Pp. 3-125 (Oxford and New York: Pergamon Press, 1976.) £7.50. [226

Philosophical Transactions of the Royal Society of London. A: Mathematical and Physical Sciences. Vol. 286, No. 1331: A Theory of a Broadening of the Infrared Absorption Spectra of Hydrogen-Bonded Species. III. The Kinematic and Electronic Coupling Mechanisms. By G. N. Robertson. Pp. 25-53. UK £1.75; Overseas £1.80. Vol. 286, No. 1332: The Elastic Strain Energy of Crystallographic Shear Planes in Reduced Tungsten Trioxide. By E. Iguchi and R. J. D. Tiller. Pp. 55-85+plates 1 and 2. UK £2.30; Overseas £2.40. Vol. 286, No. 1333: The Excitation of Surface Waves Near a Cut-Off Frequency. By B. J. S. Barnard, J. J. Mahony and W. G. Pritchard. Pp. 86-123. UK £2.20; Overseas £2.30. (London: The Royal Society, 1977.) [226

Department of Health and Social Security. Whooping Cough Vaccination: Review of the Evidence on Whooping Cough Vaccination by the Joint Committee on Vaccination and Immunization. Pp. viii+38. (London: HMSO, 1977.) 85p net. [276

Intergovernmental Oceanographic Commission. Technical Series No. 12: Oceanographic Products and Methods of Analysis and Prediction. Pp. 172. (Paris: Unesco, 1977.) 206]

nature

18 August 1977

A message for them . . . or for us?

The second Voyager spacecraft is due to be launched on its trip to the outer planets on 20 August, followed 12 days later by the first Voyager spacecraft. This apparent paradox is not due to a delay of Voyager I but simply reflects the planned arrival times of the two spacecraft at Jupiter. Voyager I, having taken a faster route, should arrive four months ahead of Voyager II. The nomenclature is therefore sensible. But is the better-known decision, to place a phonograph record on board each spacecraft, also sensible?

As the two spacecraft will fly past the outer planets and then leave the solar system for ever to wander amongst the stars, this provides a unique opportunity to signal our presence to anyone out there by using the Voyager mission as an interstellar message in a bottle. The message consists of a record containing pictorial information about the solar system and its inhabitants, messages in 60 languages and a selection of music. But cold calculation shows that the probability of this message being picked up in the awesome emptiness of space is negligibly small. Measured by its chance of success, this is a futile gesture.

Nevertheless the gesture is worth making; it is an exercise designed more for the benefit of the sender than the supposed recipient and, as Carl Sagan puts it, "the launching of this bottle into the cosmic ocean says something very hopeful about life on this planet". It is an act as apparently pointless but as understandable as leaving a flag on a conquered mountain peak. Objectively the space in the climber's rucksack would be better occupied by an extra pair of socks but, such is the essential optimism and arrogance of the human race, no one objects to such acts.

We can take comfort too from the contents of our message. President Carter states on the record: "We human beings are still divided into nation states, but these states are rapidly becoming a single global civilisation". Presumably he is working on a cosmic time scale—or maybe he knows something we don't. But this process cannot have been accelerated by the omission of reference to the Soviet Union on the record. Although NASA points out that a picture of sprinters has "Valeri Borzov in the lead", this cosmic gesture has missed the opportunity to make a worthwhile worldly one.

Voyager is more than an interstellar envelope, of course, being part of a programme of planetary exploration. But the programme's future is far from certain, so the inclusion on the Voyager records of the names of the members of the US Congress may ensure a sympathetic response in certain quarters. Similarly, with the costs so great continued public interest is a vital prerequisite for the acceptability of future missions, as Viking showed; the very name Voyager was chosen to fire the public imagination, and NASA takes seriously and performs professionally its tactical duty to educate and explain.

How much more than an interstellar envelope Voyager is, however, is too easily overlooked. The continued emphasis on the search for life has its dangers and has now reached the stage where it has become a betrayal of the broader aims of the scientific community. The tactic did not work with Viking, the common conclusion being that it was an expensive mission that did not provide a clear answer to the one question it supposedly set out to solve. That defines Viking as a failure. Using a similar motivation for Voyager would be a mistake.

NASA does not of course claim that the inclusion of a message is in any sense the motive for the mission, but it is giving the message wide publicity. And this is where the danger lies. The science correspondent who has the tough task of explaining a complicated topic to the public has been handed a gift on a plate: a sellable subject that is easy to write about and, more importantly, liable to get into print. Most science stories get written but not printed. Science writers can use the 'search for life' peg to get a story accepted and then produce a balanced report.

But how many will do this? It happened all too rarely with Viking outside the specialist science press, and so far it has not happened widely with Voyager. The same problem occurs outside the space programme too: how often have we been told, for example, that current research on fusion energy promises inexhaustible supplies of fuel with no radioactive waste? Such myths may help with funding in the short term, but the eventual backlash could be serious.

By the way, we understand that the Voyager spacecraft will send back some sort of data as they pass the outer planets carrying our message into the void. □

Heading for Honolulu

The World Psychiatric Association is about to discuss the misuse of psychiatry. **Vera Rich** considers the Soviet example

WHEN the Sixth World Congress of the World Psychiatric Association (WPA) opens in Honolulu on 28 August, one of the major issues it will discuss is the misuse of psychiatry as a means of repressing political dissent. But with opinions divided over the proper measures needed to combat this abuse, the Congress could face unprecedented controversy.

Some of the seeds of this controversy are to be found in the Soviet Union. Over the past few years, a growing body of information has reached the outside world on the confinement of political dissidents in Soviet mental hospitals. The political abuse of psychiatry is not a specifically Soviet phenomenon—there are reports of 'psychiatric torture' in certain countries of South America, and occasional reports from Eastern Europe of psychiatric measures being taken against would-be emigrants or other protesters. No other country, however, provides such a bulk of material, nor so many well-documented cases.

Public awareness in the West was first drawn to the possibility of political misuse of psychiatry in the Soviet Union in 1965, with the publication in Britain of a book by Valerii Tarsis entitled *Ward 7*. This work was essentially an autobiography disguised as a novel. Within a few years, several individual cases of such abuse made headline news—notably those of Aleksandr Esenin-Volpin, the mathematician, and Zhores Medvedev, the geneticist. The full extent of the problem only became apparent, however, in March 1971, when the International Committee for the Defence of Human Rights in Paris received over 150 pages of documentation, including what were claimed to be exact copies of official forensic reports on dissidents.

Scrutinised

During the course of the year the documents, which became known as the Bukovskii papers (after their compiler), were scrutinised by Sovietologists and psychiatrists. When the WPA held its Fifth Congress in Mexico in November 1971, strenuous efforts were made to discuss the Bukovskii material. Any firm action, however, was blocked by the Secretary-General of the WPA, Dr Denis Leigh, who averred that nothing in the WPA statutes mentioned that the WPA was responsible for ethical aspects of psychiatry. Nor, he suggested, was there any statute relating to complaints made by one member society against another.

These claims do not seem to agree with the provision in the statutes that indicates membership of the WPA, both for individuals and societies, may be terminated *inter alia* by suspension. If the WPA cannot deal with such complaints, it is difficult to see on what grounds a member society can be suspended. Dr Leigh contented himself by announcing that the complaints had been "referred to the appropriate quarter, in this case the All-Union Society of Neuropathologists and Psychiatrists"—the very body being complained about. An Ethical Committee was set up to discuss the ethics of psychiatric practice and to draw up an appropriate code of behaviour, to be discussed at the next Congress.

This decision did little to ameliorate things. Indeed, according to former internees, including Bukovskii himself and Viktor Fainberg, conditions for dissidents in mental hospitals, which had been relaxed somewhat immediately prior to the Mexico meeting, became far more stringent once it was clear that the WPA was not prepared as a body to make a stand on this issue. Dr Gary Low-Beer of Horton Hospital, an active member of the Working Group on the Internment of Dissenters in Mental Hospitals, commented that it was not necessary to have a committee to define the ethics of the issue; what was needed was some means of enforcing the accepted ethical standards.

Since the Mexico Congress, the

Bukovskii evidence has been substantiated by a number of other dissident sources, including two Soviet psychiatrists—Semeon Gluzman (now in a labour camp), who exposed the official chicanery that led to a diagnosis of insanity in the case of General Grigorenko, and Marina Voikhanskaya (now resident in London), who refused to administer punitive doses of psychotropic drugs to sane dissidents. According to Dr Leigh himself, even the Soviet delegates at Mexico were prepared to concede that the case reports in the Bukovskii material were authentic. More recently, the Soviet line when releasing a dissident has been that he or she had been insane but was now cured by Soviet medicine. Independent examination of those internees released to the West immediately after discharge from 'hospital' fail to show, however, that any psychosis had been present.

Pattern well known

The general pattern of confinement of political and religious dissidents is now well known: massive punitive doses of drugs, physical restraint, including wrapping the patient in wet canvas which shrinks as it dries, brutal treatment by convict-warders and so on. What still remains in doubt is the stand the WPA should and will take in the matter.

The report of the Ethical Committee will be presented at Honolulu and debated in plenary session. This document will cover a number of issues, including questions of consent to radical forms of treatment, safeguards in the case of involuntary commital, and so forth. So far as is known, the problem of political misuse does not feature specifically, but is contained implicitly in the topic of when treatment is not indicated.

At the General Assembly, however, which represents all 75 member societies, the problem will be specifically raised: the Royal College of Psychiatrists is presenting a motion that the WPA should condemn the Soviet practice of confining dissidents in psychiatric institutions. This motion is not likely to pass unopposed; a number of psychiatrists would prefer to keep 'political issues' out of the Congress, fearing that if the Russians walk out in protest, it would destroy any possibility of diplomatic negotiation. Commenting on this approach, Dr Harold Merskey of the University of Western Ontario observes that the WPA is not an international body like the UN, whose sole purpose is to keep diplomatic channels open; it is a professional body, he says, representing a profession in which ethical standards are all-important in any meaningful international exchange. He further remarks that "if politics have appeared in the matter, it is the Russians who have introduced them".

A special meeting to discuss individual abuses has been called on the initiative of the American Psychiatric Association; Dr Voikhanskaya is to be one of the floor speakers. The French Committee against Psychiatric Abuse is planning a rally outside the official context of the Congress. The problem underlying all such discussions and protests still remains unsolved: how far is the Soviet psychiatric profession committed to such abuses? And, following from this, what should the stance of individual psychiatrists and psychiatric bodies abroad be?

During the past few years, there has been a certain 'liberalisation' of Soviet psychological and psychiatric theory. This is reflected even in the new (1975) edition of the Large Soviet Encyclopædia. Whereas the previous edition (1955) dismisses psychoanalysis as a "bourgeois pseudo-science", the new version, though still condemning "idealistic" tendencies such as "Freudism", nevertheless acknowledges that the analytic approach has brought into scientific consideration such "important phenomena" as unconscious processes and the effect of the experiences of early childhood.

The historical survey places far less emphasis on Pavlov, who does not even merit a special biographical note, and the former description of psychiatric treatment as the eradication of harmful reflexes and the implantation of healthy ones has been replaced by a less simplistic one. Nor is it any longer stated that psychological "reality" must be understood in the sence of Marxist-Leninist reality. At first glance, the new entries seem almost as hopeful for Soviet psychiatry as the refutation of Lysenkoism was for genetics.

Marxist–Leninist science

Nevertheless, since Marxist–Leninism is considered to be a science in its own right and the basis of all Soviet science the outlook is not promising for those psychiatric 'patients' who hold opposing philosophies. The somewhat bizarre diagnoses such as "schizophrenia with delusions of reformism" may, in practice, be simply a useful tag for dropping a political nuisance into a psychiatric oubliette; but the Soviet psychiatric system provides a background that is particularly amenable to such distortions. The Soviet physicians' oath contains a pledge "to be guided by the principles of communist morality"—principles which specifically put the good of the community above that of the individual.

Certainly, many Soviet psychiatrists are unaware of the abuses. Dr Voikhanskaya states that she herself knew nothing of them for almost ten years; others, at great personal risk, refuse to participate in them. The problem of political psychiatric abuse in the Soviet Union is not, however, simply that of a relatively small number of psychiatrists putting their devotion to the establishment above their professional commitment; any serious consideration of the problem, or plan to protest, must pay serious attention to the background against which they arise and within which they can acquire some kind of 'socio-political' justification. ☐

Bukovskii: sent documents
